Abstract

27

The purpose of this thesis was to use Convolutional Neural Networks
28 (CNN) to separate μ' s and π' s for use in increasing the acceptance rate
29 of μ' 's below the implemented 75cm track length cut in the Charged
30 Current Inclusive (CC-Inclusive) event selection for the CC-Inclusive
31 Cross-Section Measurement. In doing this, we increase acceptance
32 rate for CC-Inclusive events below a specific momentum range.

33

Dedication

34

I dedicate this dissertation to the two important women in my life; My
35 wife and my mom. Both have been there cheering me on giving me strength
36 and love as I worked towards the hardest accomplishment I've ever done.

37

Jessica Nicole Esquivel

¹³⁹	4.2a	Predicted distribution of flash times with respect to trigger time for 1 day of data taking at nominal rate and intensity	31

141	4.2b Measured distribution of flash times with a 50 PE threshold cut, with respect to trigger time. Shown as a ratio to the expected cosmic rate from off-beam data. A clear excess from neutrinos is visible between 3- 5 μ s after the trigger time.	31
145	4.3 Percent of good clusters remaining for neutrinos and cosmics after the primary cuts were applied. This is relative to total number of initial clusters.	32
148	4.4 Percent matched cluster pairs remaining for neutrinos and cosmics after secondary cuts applied. This is relative to the number of events that contain clusters which pass the primary cuts.	32
151	5.1 5.1a Track range distribution for selection I. The track range is defined as the 3D distance between the start and end of the muon candidate track. No data is shown below 75 cm due to the track length cut described previously. 5.1b Efficiency of the selected events by process quasi-elastic (QE), resonant (RES), and deep-inelastic (DIS). Statistical uncertainty is shown in the bands and the distributions are a function of true muon momentum. The rise of the efficiency between 0 GeV and 0.5 GeV is due to the minimum track length cut and the decreasing efficiency for higher momentum tracks is caused by the containment requirement. .	38
160	5.1a Track range distribution of selection I	38
161	5.1b Selection efficiency as a function of the true muon momentum .	38
162	5.2 Time distribution of reconstructed optical flashes with a PE value of 50 or more for a sample of BNB unbiased triggered events.	40
164	5.3 Flash time distribution for all flashes (left plot) and flashes > 20PE (right plot). The different curves are as follows: on-beam data (black), off-beam data (red), CORSIKA inTime MC (light blue), BNB only MC (green), and BNB+Cosmic MC (purple). The dashed vertical lines mark the time window that was chosen for each sample	41
169	5.4 Reconstruction chain run on both data and MC. The red stars mean that the algorithm returns reconstructed 3D vertices.	42

171	5.5 Event selection diagram for selection I and selection II. This analysis focused on optimizing selection I. Boxes with the same color across the two selections symbolize similar cuts.	47
174	5.6 MC momentum distributions of the muon originating from a ν_μ CC interaction. Upper left is the momentum distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the momentum distribution after the selection (red). The lower plot is the selection efficiencies.	50
180	5.7 MC $\cos(\theta)$ distributions of the muon originating from a ν_μ CC interaction. Upper left is the $\cos(\theta)$ distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the $\cos(\theta)$ distribution after the selection (red). The lower plot is the selection efficiencies.	51
185	5.8 MC ϕ distributions of the muon originating from a ν_μ CC interaction. Upper left is the ϕ distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the ϕ distribution after the selection (red). The lower plot is the selection efficiencies.	52
190	5.9 MC momentum distributions of the muon originating from a ν_μ CC interaction. Upper left is the momentum distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the momentum distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.	53
197	5.10 MC $\cos(\theta)$ distributions of the muon originating from a ν_μ CC interaction. Upper left is the $\cos(\theta)$ distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the $\cos(\theta)$ distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.	54

204	5.11 MC ϕ distributions of the muon originating from a ν_μ CC interaction. Upper left is the ϕ distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the ϕ distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.	55
211	6.1 Pixel representation and visualization of a curve detector filter. As you can see, in the pixel representation, the weights of this filter are greater along a curve we are trying to find in the input image	59
214	6.2 Visualization of filters found in first layer of a CNN.	59
215	6.3 Applying a feature mask over a set of fashion items to extract necessary information for auto-encoding. Unnecessary information for example color or brand emblems are not saved. This feature map is an edge detec- tion mask that leaves only shape information which helps to distinguish between different types of clothes.	60
220	6.4 Pictorial Representation of Convolutional Neural Networks as well as a visual representation on CNN's complexity of layer feature extraction	60
222	6.5 Pictoral representation of the AlexNet model. The AlexNet model consists of 5 convolution layers and 3 fully connected layers.	63
224	6.6 Pictoral representation of the GoogleNet model. The GoogleNet model consists of 22 layers. The model implements 9 Inception modules which performs covolution and pooling in parallel and strays away from the basis that CNN layers need to be stacked up sequentially. The GoogleNet model also doesn't use fully connected layers, instead it uses average pooling which greatly reduces the amount of parameters. GoogleNet has 12x fewer parameters than AlexNet.	63
231	7.1 Accuracy vs. Loss of ImageNet 2-output μ/π sample consisting of 10000 images each.	69

233	7.2 Description of confusion matrix variables: False pion rate = $false\pi/total\pi$	
234	True pion rate = $true\pi/total\pi$ Accuracy = $(true\pi rate + true\mu rate)/2$	
235	Pion prediction value = $true\pi/(true\pi + false\pi)$ Muon prediction value	
236	= $true\mu/(true\mu + false\mu)$ 7.2c The probability plot includes muons and	
237	pions that are classified as primary particles.	70

List of tables

354	4.1	Passing rates for 2D cluster cuts for neutrino on MC set and a cosmic only MC set. First column shows event rates with no cuts applied to both sets. Columns two and three show event rates after primary and secondary cuts are applied. Line three shows the second line scaled with the flash finding factor of 0.008. All events are normalized to per day assuming we are running at 5 Hz.	31
361	5.1	Passing rates of Selection I. Numbers are absolute event counts and cosmic background is not scaled. The BNB+Cosmic sample contains all events, not just ν_μ CC inclusive. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt total generated events (second percentage). The BNB+Cosmic MC-Truth column shows how many true ν_μ CC inclusive events are left in the sample. This number includes mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The cosmic only sample is used just to illustrate the cut efficiency. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in section 5.2.	48
373	5.2	Passing rates for Selection I selection applied to on-beam and off-beam data. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). Off-beam data has been scaled with a factor 1.23 to normalize to the on-beam data stream.	48

378	8.1 Comparing passing rates of CNN at different probabilities versus 75 cm track length cut: Numbers are absolute event counts and Cosmic background is not scaled appropriately. The BNB+Cosmic sample contains all events. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). In the BNB+Cosmic MC Truth column shows how many true ν_μ CC-inclusive events (in FV) are left in the sample. This number includes possible mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The CNN MC True generated events were scaled wrt the MC True generated events for the 75 cm cut passing rates due to only running over 188,880 generated events versus the 191362 generated events. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in [?]. Note that these numbers are not a purity, since other backgrounds can't be determined at this step. . .	94
394	8.2 Signal and background event numbers at modified selection level with CNN cut estimated from a BNB+Cosmic sample and Cosmic only sample normalized to $5 * 10^{19}$ PoT. The last column gives the fraction of this signal or background type to the total selected events per CNN probability.	94

*"If they don't give you a seat at the table,
bring a folding chair."*

— Shirley Chisholm

401 **Chapter 1**

402 **Introduction**

403 This thesis will be a description of work done to further increase efficiency and purity
404 of the charged current inclusive cross section measurement using the MicroBooNE
405 detector. It will also describe the MicroBooNE detector, what neutrinos are, the
406 charged current inclusive cross section measurement and its importance as well as
407 convolutional neural networks and how they can be used in μ/π separation. Chapter
408 **2** will talk about the background of neutrinos and the people and detectors that
409 discovered neutrinos as well as an in depth history of neutrino oscillation and the
410 discovery that neutrinos have mass.

411 Chapter **3** will discuss the MicroBooNE experiment, specifically, how Liquid
412 Argon Time Projection Chambers work, the Light Collection System and the Electronic
413 and Readout Trigger systems. This chapter will also describe the Booster Neutrino
414 Beam sationed at Fermilab.

415 Chapter **4** will discuss the work that was done to detect the first neutrinos seen in
416 the MicroBooNE detector and the software reconstruction efforts required to create an
417 automated neutrino ID filter that was used to find the first neutrinos and then was
418 later expanded on to create the charged current inclusive filter that will be discussed
419 in chapter **5**

420 Chapter **6** will give a brief description of what Convolutional Neural Networks are
421 and how it will be used for μ/π separation in this selection. Chapter **7** will discuss
422 the hardware frameworks and training methods used to train multiple Convolutional
423 Neural Networks for use in the charged current inclusive cross section measurement.
424 Chapters **8** and **??** will discuss the results of using Convolutional Neural Networks on
425 monte-carlo and data to sift out charged current inclusive neutrino events.

⁴²⁶ Chapter 2

⁴²⁷ Neutrinos

⁴²⁸ 2.1 What are Neutrinos

⁴²⁹ Neutrinos are one of the fundamental particles which make up the universe. They are
⁴³⁰ also one of the least understood. Neutrinos are not affected by the electromagnetic
⁴³¹ forces because they do not have electric charge. Neutrinos are affected by a "weak"
⁴³² sub-atomic force of much shorter range than electromagnetism, and are therefore able
⁴³³ to pass through great distances in matter without being affected by it. Until the late
⁴³⁴ 90's, neutrinos were thought to have no mass. Due to their mass, neutrinos are also
⁴³⁵ affected by gravity. Neutrinos are created by radioactive decay or nuclear reactions
⁴³⁶ such as the ones that happen in the sun, in nuclear reactors or when cosmic rays hit
⁴³⁷ atoms. There are three types of neutrinos, ν_e , ν_μ and ν_τ which correspond to their
⁴³⁸ charged lepton pairs.

⁴³⁹ As previously stated, neutrinos are very weakly interacting; in fact, neutrinos can
⁴⁴⁰ pass unscathed through a wall of lead several hundred light-years thick. Because
⁴⁴¹ neutrinos interact so rarely, studying neutrinos requires a massive detector and a
⁴⁴² powerful neutrino source. With that being said, we can only infer their existence when
⁴⁴³ they interact in a detector. In a collision, distinct charged particles are produced with
⁴⁴⁴ each type of neutrino. An electron neutrino will create an electron, a muon neutrino
⁴⁴⁵ will create a muon, and a tau neutrino will create a tau. The track the particle leaves
⁴⁴⁶ in the detector is how one figures out what type of neutrino interaction was "seen".
⁴⁴⁷ Liquid Argon Time Projection Chambers are the newest type of detectors being used to
⁴⁴⁸ study neutrinos due to their excellent imaging and particle identification capabilities.

⁴⁴⁹ 2.2 History of Neutrinos

⁴⁵⁰ The neutrino was first postulated by Wolfgang Pauli in 1931 to explain how beta
⁴⁵¹ decay could resolve the conservation of energy, momentum and angular momentum
⁴⁵² problem. Pauli suggested that this missing energy might be carried off, unseen, by a
⁴⁵³ neutral particle (he called neutron) which was escaping detection. James Chadwick
⁴⁵⁴ discovered a much heavier nuclear particle in 1932 that he also named neutron, leaving
⁴⁵⁵ two particles with the same name. Enrico Fermi was the first person to coin the
⁴⁵⁶ term neutrino (which means little neutral one in latin) in 1933 to fix this confusion.
⁴⁵⁷ Fermi's paper, which was published in 1934, unified Pauli's neutrino with Paul Dirac's
⁴⁵⁸ positron and Werner Heisenberg's neutron-proton model and his theory accurately
⁴⁵⁹ explained many experimentally observed results. Wang Ganchang first proposed the
⁴⁶⁰ use of beta capture to experimentally detect neutrinos and in 1959 Clyde Cowan and
⁴⁶¹ Frederick Reines published their work stating that they had detected the neutrino.
⁴⁶² The experiment called for antineutrinos created in a nuclear reactor by beta decay that
⁴⁶³ reacted with protons producing neutrons and positrons: $\nu_e + p^+ \rightarrow n^0 + e^+$. Once
⁴⁶⁴ this happens, the positron finds an electron and they annihilate each other and the
⁴⁶⁵ resulting gamma rays are detectable. The neutron is detected by neutron capture and
⁴⁶⁶ the releasing of another gamma ray. In 1962 Leon M. Lenderman, Melvin Schwartz
⁴⁶⁷ and Jack Steinberger were the first to detect interactions of the muon neutrino. The
⁴⁶⁸ first detection of the tau neutrino was announced in the summer of 2000 by the
⁴⁶⁹ DONUT collaboration at Fermilab. In the late 1960s, many experiments found that the
⁴⁷⁰ number of electron neutrinos arriving from the sun was around 1/3 to 1/2 the number
⁴⁷¹ predicted by the Standard Solar Model. This became known as the solar neutrino
⁴⁷² problem and remained unresolved for around thirty years. This problem was resolved
⁴⁷³ by the discovery of neutrino oscillation and mass. [1]

⁴⁷⁴ 2.3 Neutrino Oscillations

⁴⁷⁵ Neutrino oscillation was first predicted by Bruno Pontecorvo. It describes the phe-
⁴⁷⁶ nomenon of a neutrino created with a specific lepton flavor (electron, muon or tau)
⁴⁷⁷ that is later measured to have a different flavor. Neutrino oscillation is important
⁴⁷⁸ theoretically and experimentally due to the fact that this observation implies that the
⁴⁷⁹ neutrino has a non-zero mass, which is not part of the original Standard Model of
⁴⁸⁰ particle physics. [2]

481 2.3.1 Solar Oscillations and the Solar Neutrino Problem

482 The solar neutrino flux derived from Bahcall's Standard Solar Model is shown in figure
 483 2.1. Nuclear fusion and decay processes produce an abundant amount of neutrinos.
 484 The standard solar model predicts that these reactions produce several groups of
 485 neutrinos, each with differing fluxes and energy spectra. The figure also shows the
 486 ranges of detection of existing solar neutrino experiments in different shades of blue
 487 to illustrate that they sample different portions of the solar neutrino energy spectrum.
 488 Three of these experiments, plus a new one, are discussed below.

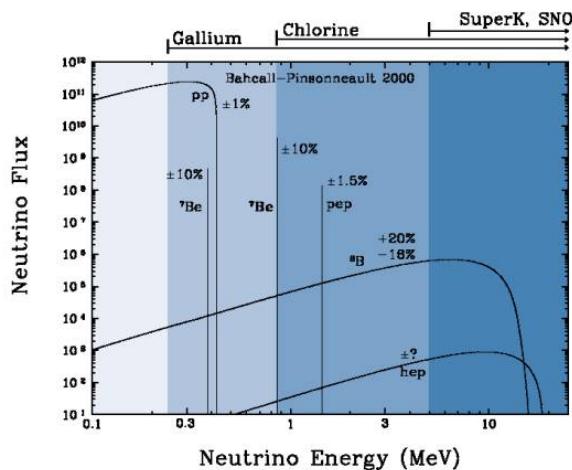

Figure 2.1: The Standard Solar Model

489 Since neutrinos rarely interact with matter, they pass through the sun and the earth
 490 undetected. About 65-billion neutrinos from the sun stream through every square
 491 centimeter on the Earth every second, yet we are oblivious to their passage in our
 492 every-day lives. [3]

493 The first experiment to detect the effects of neutrino oscillation was the Ray Davis's
 494 Homestake Experiment. The detector was stationed in the Homestake Gold Mine in
 495 Lead, South Dakota. It was 1,478 meters underground and was $380\ m^3$. The detector
 496 was filled with perchloroethylene. Perchloroethylene was chosen because of its high
 497 concentrations of chlorine. When an ν_e interacted with chlorine-37 atom, the atom
 498 would transform to argon-37 which was then extracted and counted. The neutrino
 499 capture reaction is shown in equation 2.1. Davis observed a deficit of about 1/3
 500 the flux of solar neutrinos that was predicted by Bahcall's Standard Solar Model.

501 The unexplained difference between the measured solar neutrino flux and model
 502 predictions lead to the Solar Neutrino Problem. [4]

503 While it is now known that the Homestake Experiment detected neutrinos, some
 504 physicist were weary of the results. Conclusive evidence of the Solar Neutrino Problem
 505 was provided by the Kamiokande-II experiment, a water Cherenkov detector with
 506 a low enough energy threshold to detect neutrinos through neutrino-electron elastic
 507 scattering. In the elastic scattering interaction the electrons coming out of the point of
 508 reaction strongly point in the direction that the neutrino was traveling, away from the
 509 sun. While the neutrinos observed in Kamiokande-II were clearly from the sun, there
 510 was still a discrepancy between Kamiokande-II and Homestake; The Kamiokande-
 511 II experiment measured about 1/2 the predicted flux, rather than the 1/3 that the
 512 Homestake Experiment saw.

513 The solution to the solar neutrino problem was finally experimentally determined
 514 by the Sudbury Neutrino Observatory(SNO). The Ray Davis's Homestake Experiment
 515 was only sensitive to electron neutrinos, and the Kamiokande-II Experiment was
 516 dominated by the electron neutrino signal. The SNO experiment had the capability to
 517 see all three neutrino flavors. Because of this, it was possible to measure the electron
 518 neutrinos and total neutrino flux. The experiment demonstrated that the deficit was
 519 due to the MSW effect, the conversion of electron neutrinos from their pure flavor
 520 state into the second neutrino mass eigenstate as they passed through a resonance
 521 due to the changing density of the sun. The resonance is energy dependent, and is
 522 visible near 2MeV. The water cherenkov detectors only detect neutrinos above about
 523 5MeV, while the radiochemical experiments were sensitive to lower energy (0.8MeV
 524 for chlorine, 0.2MeV for gallium), and this turned out to be the source of the difference
 525 in the observed neutrino rates at the two types of experiments. Figure 2.2 shows
 526 Homestake, Kamiokande-II and SNO experiments.

527 MSW Effect

528 The Mikheyev-Smirnov-Wolfenstein effect is a process which acts to modify neu-
 529 trino oscillations in matter. The presence of electrons in matter changes the energy

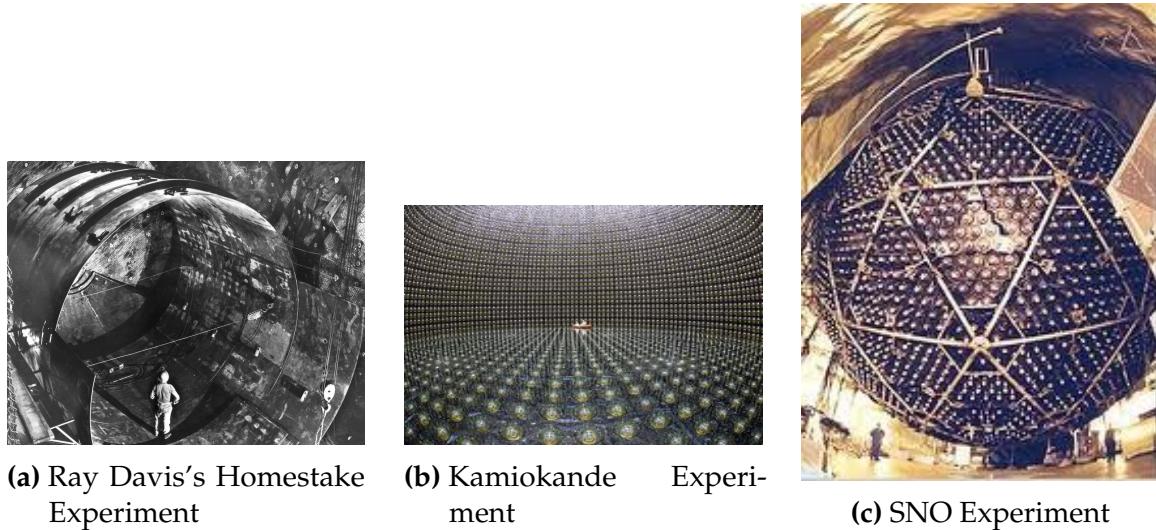

Figure 2.2: Solar Neutrino Experiments

530 levels of the mass eigenstates of neutrinos due to charged current coherent forward
 531 scattering of the electron neutrinos. This coherent forward scattering is similar to
 532 the electromagnetic process with respect to the refractive index of light in a medium.
 533 Because of this MSW Effect, neutrinos in vacuum have a different effective mass than
 534 neutrinos in matter and because neutrino oscillations depend on the squared mass
 535 difference of the neutrinos, the neutrino oscillations are different in matter than in
 536 vacuum. This effect is important at the sun where electron neutrinos are produced.
 537 The neutrinos of high energy leaving the sun are in a vacuum propagation eigenstate
 538 ν_2 that has a very small overlap with the electron neutrino $\nu_e = \nu_1 \cos(\theta) + \nu_2 \sin(\theta)$
 539 seen by the charged current reactions in Kamiokande-II and SNO. The discrepancy of
 540 the deficit between SNO, Kamiokande-II and Homestake is due to the energy of the
 541 solar neutrinos. The MSW effect "turns on" at about 2MeV and at lower energies, this
 542 MSW effect is negligible. [5]

543 **2.3.2 Atmospheric Oscillations and the Atmospheric Neutrino 544 Anomaly**

545 Atmospheric neutrinos are neutrinos that stem from the decay hadrons coming from
 546 primary cosmic rays. The dominant part of the decay chain is shown in equations 2.2
 547 and 2.3

$$\pi^+ \rightarrow \mu^+ \nu_\mu \mu^+ \rightarrow e^+ \nu_e \bar{\nu}_\mu \quad (2.2)$$

548

$$\pi^- \rightarrow \mu^- \bar{\nu}_\mu \mu^- \rightarrow e^- \bar{\nu}_e \nu_\mu \quad (2.3)$$

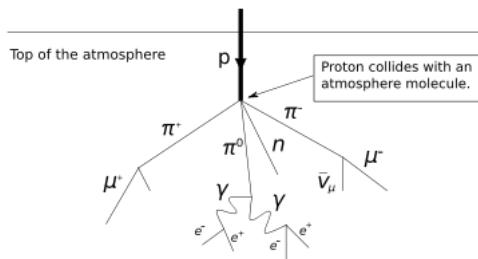

Figure 2.3: Cosmic Ray Shower

549 Figure 2.3 shows the cosmic ray shower. In general, these neutrinos have energies
 550 from 1GeV to 100s of GeV and the ratio of ν_μ s to ν_e s equals to 2 (see equation 2.4)

$$R = \frac{(\nu_\mu + \bar{\nu}_\mu)}{(\nu_e + \bar{\nu}_e)} \quad (2.4)$$

551 There have been two types of detectors used to study atmospheric neutrinos: Water
 552 Cherenkov detectors and tracking calorimeters. Super-Kamiokande is the detector we
 553 will focus on. These atmospheric detector experiments measure the ratio of ν_μ to ν_e .
 554 They also measure the zenith angle distribution of the neutrinos. These experiments
 555 report a double ratio (shown in equation 2.5). This double ratio is the ratio measured
 556 in the detector to the ratio that's expected which is 2. If the double ratio equals to 1, the
 557 data agrees with the prediction. Various measurements from multiple experiments
 558 are shown in figure 2.4. Except for Frejus, all R measurements are less than 1. This
 559 discrepancy between the predicted R and the measured R became known as the
 560 Atmospheric Neutrino Anomaly.

$$R = \frac{(N_\mu / N_e)_{DATA}}{(N_\mu / N_e)_{SIM}} \quad (2.5)$$

561 Kamiokande-II has the the capability of measuring the direction of the incoming
 562 neutrinos. The expectation of atmospheric neutrino detection is that the flux be

Experiment	Type of experiment	R
Super-Kamiokande	Water Cerenkov	0.675 ± 0.085
Soudan2	Iron Tracking Calorimeter	0.69 ± 0.13
IMB	Water Cerenkov	0.54 ± 0.12
Kamiokande	Water Cerenkov	0.60 ± 0.07
Frejus	Iron Tracking Calorimeter	1.0 ± 0.15

Figure 2.4: Measurements of the double ratio for various atmospheric neutrino experiments

isotropic due to the fact that atmospheric neutrinos can reach the detector from all directions. Kamiokande-II noticed that muon-like data did not agree well with this expectation. At low energies approximately half of the ν_μ are missing over the full range of zenith angles. At high energies the number of ν_μ coming down from above the detector seems to agree with expectation, but half of the same ν_μ coming up from below the detector are missing. This anomaly can be easily explained by neutrino flavor oscillations. Due to the fact that the neutrino travels less distance coming straight down into the detector (about 15km) than coming up from the bottom of the detector(13000km) changes the probability of oscillation. The probability of oscillation for the muon neutrinos coming down into the detector is roughly zero, whereas for neutrinos coming up, the oscillation probability is $\sin^2(2\theta)$. Both the solar and atmospheric neutrino problems can be explained by neutrino oscillation so its fitting to derive this phenomenon mathematically. In the next two sections, two flavor and three flavor neutrino oscillation derivations will be explained.

2.3.3 Two Flavor Neutrino Oscillation Formulation

The flavor eigenstates can oscillate between each other because they are composed of an add-mixture of mass eigenstates(ν_1, ν_2). Figure 2.5 shows the mass and flavor eigenstates rotated by an angle θ which is the mixing angle.

In matrix form the wavefunctions are:

$$\begin{pmatrix} \nu_\mu \\ \nu_e \end{pmatrix} = \begin{pmatrix} \cos\theta & \sin\theta \\ -\sin\theta & \cos\theta \end{pmatrix} * \begin{pmatrix} \nu_1 \\ \nu_2 \end{pmatrix} \quad (2.6)$$

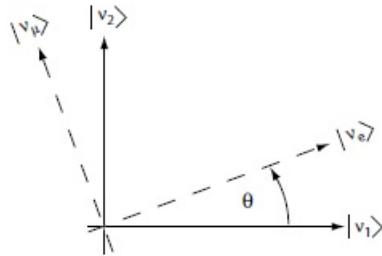

Figure 2.5: The flavor eigenstates are rotated by an angle θ with respect to the mass eigenstates

582 Applying the time evolution operator to ν_μ :

$$|\nu_\mu(t)\rangle = -\sin\theta|\nu_1\rangle e^{-i\frac{E_1 t}{\hbar}} + \cos\theta|\nu_2\rangle e^{-i\frac{E_2 t}{\hbar}} \quad (2.7)$$

583 where $E_1 = \sqrt{p^2 c^2 + m_1^2 c^4}$ and $E_2 = \sqrt{p^2 c^2 + m_2^2 c^4}$ and $p_1 = p_2$. For the time
 584 being, let us assume $\hbar = c = 1$. With this assumption: $E_1 = \sqrt{p^2 + m_1^2}$ and $E_2 =$
 585 $\sqrt{p^2 + m_2^2}$. The next modifications is to assume neutrinos are relativistic:

$$\gamma = \frac{E}{m_o c^2} = \frac{\sqrt{p^2 c^2 + m_o^2 c^4}}{m_o c^2} \gg 1 \quad (2.8)$$

586 because of this,

$$p \gg m_o \quad (2.9)$$

587

$$E = \sqrt{p^2 + m_o^2} = p\sqrt{1 + m_o^2/p^2} \simeq p + \frac{1}{2}\frac{m_o^2}{p} \quad (2.10)$$

588 where the binomial expansion is used. Now E_1 and E_2 can be written as:

$$E_1 \simeq p + \frac{1}{2}\frac{m_1^2}{p} \text{ and } E_2 \simeq p + \frac{1}{2}\frac{m_2^2}{p} \quad (2.11)$$

589 Now applying all these assumptions back into equation 2.7 gives us:

$$|\nu_\mu(t)\rangle = -\sin\theta|\nu_1\rangle e^{-i\left(p + \frac{1}{2}\frac{m_1^2}{p}\right)t} + \cos\theta|\nu_2\rangle e^{-i\left(p + \frac{1}{2}\frac{m_2^2}{p}\right)t} \quad (2.12)$$

$$|\nu_\mu(t)\rangle = e^{-i\left(p+\frac{1}{2}\frac{m_1^2-m_2^2}{p}\right)t} (-\sin\theta|\nu_1\rangle + \cos\theta|\nu_2\rangle) \quad (2.13)$$

⁵⁹⁰ Substituting $\Delta m^2 = m_1^2 - m_2^2$ and $t = \frac{x}{c} = x$ and $e^{-iz} = e^{-i\left(p+\frac{1}{2}\frac{m_1^2}{p}\right)t}$ gives us:

$$|\nu_\mu(t)\rangle = e^{-iz} \left(-\sin\theta|\nu_1\rangle + \cos\theta|\nu_2\rangle e^{+ix\left(\frac{1}{2}\frac{\Delta m^2}{p}\right)} \right) \quad (2.14)$$

⁵⁹¹ Finding the Probability for a $\nu_\mu \rightarrow \nu_e$:

$$P(\nu_\mu \rightarrow \nu_e) = |\langle \nu_e | \nu_\mu(t) \rangle|^2 \quad (2.15)$$

⁵⁹² Remembering that $\langle \nu_i | \nu_j \rangle = \delta_{ij}$

$$\langle \nu_e | \nu_\mu(t) \rangle = e^{-iz} \left(-\sin\theta\cos\theta + \sin\theta\cos\theta e^{\frac{i\Delta m^2 x}{p}} \right) \quad (2.16)$$

⁵⁹³ Taking the absolute value squared gives us:

$$P(\nu_\mu \rightarrow \nu_e) = |\langle \nu_e | \nu_\mu(t) \rangle|^2 = e^{+iz} e^{-iz} \sin^2\theta \cos^2\theta \left(-1 + e^{\frac{i\Delta m^2 x}{p}} \right) \left(-1 + e^{\frac{-i\Delta m^2 x}{p}} \right) \quad (2.17)$$

⁵⁹⁴ Since the neutrino is relativistic we can set $p = E_\nu$ and change $x = L$. Also
⁵⁹⁵ recognizing the trigonometric relation $(1 - \cos 2\theta)/2 = \sin^2\theta$ the above equation
⁵⁹⁶ becomes:

$$P(\nu_\mu \rightarrow \nu_e) = \sin^2 2\theta \sin^2 \left(\frac{\Delta m^2 L}{4E_\nu} \right) \quad (2.18)$$

⁵⁹⁷ All that's left to do now is re-introduce \hbar and c doing this we get:

$$P_{\nu_\mu \rightarrow \nu_e}(L, E) = \sin^2 2\theta \sin^2 \left(1.27 \Delta m^2 \frac{L}{E_\nu} \right) \quad (2.19)$$

⁵⁹⁸ This equations has three important variables.

- The angle θ : This angle, as mentioned before, is called the mixing angle. It defines the difference between the flavor and the mass eigenstates. When $\theta = 0$ the mass and flavor eigenstates are identical and now oscillations occur.
- The mass squared difference, Δm^2 : Again $\Delta m^2 = m_1^2 - m_2^2$. The reason this is an important variable is because it implies that for neutrinos to oscillate, neutrinos must have mass. Furthermore, the mass squared difference also tells us that the neutrino mass eigenstates must be different.
- L/E: This is the variable that is of most interest to experimental physicists due to the fact that it is the variable that we set. L is the distance between the source and detector and E is the energy of the neutrino. For a given Δm^2 , the probability of oscillation changes with respect to L/E.

2.3.4 Three Flavor Neutrino Oscillation Formulation

Seeing the quantum mechanics involved in deriving the probability of a two flavor neutrino oscillation, it is now possible to formulate the three flavor neutrino oscillation. The three flavor neutrino oscillation formulation begins similarly to the two flavor, but there is the Pontecorvo-Maki-Nakagawa-Sakata matrix (PMNS) instead of the 2X2 matrix in the previous section. The PMNS matrix is show below:

$$\begin{pmatrix} c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta} \\ -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta} & s_{23}c_{13} \\ s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta} & c_{23}c_{13} \end{pmatrix} * \begin{pmatrix} e^{i\alpha_1/2} & 0 & 0 \\ 0 & e^{i\alpha_2/2} & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (2.20)$$

where $c_{ij} = \cos\theta_{ij}$ and $s_{ij} = \sin\theta_{ij}$

Following the same steps as before we get:

$$P_{\alpha \rightarrow \beta} = \delta_{\alpha\beta} - 4\sum Re(U_{\alpha i}^* U_{\beta i} U_{\alpha j} U_{\beta j}^*) \sin^2\left(\frac{\Delta m_{ij}^2 L}{4E}\right) 2\sum Im(U_{\alpha i}^* U_{\beta i} U_{\alpha j} U_{\beta j}^*) \sin\left(\frac{\Delta m_{ij}^2 L}{2E}\right) \quad (2.21)$$

The main things to notice here are δ_{ij} which is the CP violating term and has not been measured yet, and θ_{13} which has just been measured. CP violation is a violation

620 of the postulated CP-symmetry. CP-symmetry states that the laws of physics should
621 be the same if a particle were to be exchanged with its antiparticle and then if the left
622 hand side of a decay were switched with the right hand side.

623 **2.3.5 Reactor Oscillation**

624 Many experiments have searched for oscillation of electron anti-neutrinos produced at
625 nuclear reactors. Such oscillations give the value of the parameter θ_{13} . The KamLAND
626 experiment, started in 2002, has made a high precision observation of reactor neutrino
627 oscillation. Neutrinos produced in nuclear reactors have energies similar to solar
628 neutrinos, a few MeV. The baselines of these experiments have ranged from tens
629 of meters to over 100 km. On 8 March 2012, the Daya Bay team announced a 5.2σ
630 discovery that $\theta_{13} \neq 0$.

⁶³¹ Chapter 3

⁶³² The MicroBooNE Experiment

⁶³³ The purpose of this chapter is to discuss and understand the details of the MicroBooNE
⁶³⁴ detector. A thorough understanding of MicroBooNE and the technology behind liquid
⁶³⁵ argon time projection chambers is important for understanding results as well as
⁶³⁶ understanding how images were made for use in deep learning efforts that will be
⁶³⁷ outlined in later chapters.

⁶³⁸ 3.1 Liquid argon time projection chambers

⁶³⁹ Liquid Argon Time Projection Chambers (LArTPCs) are an exciting detector technol-
⁶⁴⁰ ogy that provide excellent imaging and particle identification, and are now being
⁶⁴¹ used to study neutrinos. The Time Projection Chamber (TPC) was first invented by
⁶⁴² Nygren in 1974 [?] and the proposal for a LArTPC for neutrino physics was made
⁶⁴³ by Rubbia [?] in 1977 with the ICARUS collaboration implementing this concept [?].
⁶⁴⁴ A LArTPC is a three-dimensional imaging detector that uses planes of wires at the
⁶⁴⁵ edge of an active volume to read out an interaction. When a neutrino interacts with an
⁶⁴⁶ argon atom, the charged particles that are produced ionize the LAr as they travel away
⁶⁴⁷ from the interaction. By placing a uniform electric field throughout the LAr volume,
⁶⁴⁸ the ionization is made to drift towards a set of anode planes, which consist of wires
⁶⁴⁹ spaced very closely together collecting the ionized charge, which is subsequently read
⁶⁵⁰ out by electronics connected to the anode wires. The collected ionization creates a
⁶⁵¹ spatial image of what happened in the detector on each anode plane. The position
⁶⁵² resolution of the interaction along the beam direction (perpendicular to drift direction)
⁶⁵³ relies on the wire pitch, while the resolution in drift direction is dependent on the

timing resolution of the electronics used and the longitudinal diffusion in the volume.
 The drift time of the ionization relative to the time of the original signal allows the
 signal to be projected back along the drift coordinate, hence the name LArTPC. Having
 very small distances between each wire within an anode plane allows for very fine
 granularity and detail to be captured, and having multiple wire planes at different
 angles provides independent two-dimensional views that can be combined into a
 three dimensional picture of the interaction. Once the charge signal is created on the
 anode planes, software analysis packages identify particles in the detector by using
 deposited energy on the wires along their track length. The 30 year development of the
 ICARUS detector has led to LArTPCs being used as cosmic ray [?], solar neutrino [?]
 and accelerator neutrino [?] detectors. The ArgoNeuT experiment at Fermilab was
 the first United States based liquid argon neutrino program that has since produced
 short-baseline $\nu - Ar$ cross-section measurements in the NUMI beamline [?]. The
 MicroBooNE experiment is the second experiment in the US based LArTPC neutrino
 program and will be discussed thoroughly in the next sections. The next phases of
 the liquid argon neutrino program are under way and are the Fermilab Short Base-
 line Neutrino (SBN) program [?] and the Deep Underground Neutrino Experiment
 (DUNE) [6]. The SBN program will include three LArTPC detectors, including the
 MicroBooNE detector, on the Booster Neutrino Beam (BNB) to do multiple-baseline
 oscillation measurements. The detector closest to the beam will be the 40 ton Short
 Baseline Neutrino Detector (SBND) [?] at 150 m and the detector furthest is the 600 ton
 ICARUS T600 [?] detector positioned at 600 m. The DUNE collaboration will deliver
 a 30 GeV neutrino beam 1300 km from Fermilab to a 34 kiloton LArTPC detector
 at Homestake, SD. DUNE will study the leptonic CP phase, δ_{cp} , as well as measure
 neutrino and antineutrino oscillations.

3.2 The MicroBooNE Time Projection Chamber

MicroBooNE (Micro Booster Neutrino Experiment) is a 89 ton active volume (180 ton
 total mass) LArTPC which is then inserted into a cylindrical cryostat on axis of the
 Booster Neutrino Beam (BNB) stationed at Fermilab in Batavia, Illinois. Understanding
 LArTPC technology and detector physics is necessary to build a LArTPC the size of
 DUNE, and MicroBooNE has made many advances in developing this technology [7]
 [8].

MicroBooNE's Time Projection Chamber (TPC) is 10.3 m long (beamline direction), 2.3 m high and 2.5 m wide (which corresponds to the drift distance). The TPC is shown in figure ?? . MicroBooNE is the largest LArTPC currently running in the world [9]. This LArTPC has 3 wire planes: 1 plane that collects the ionization in the wires and is 0° to the vertical with 3456 wires spaced 3 mm apart, and 2 planes where the ionization drifts passed and induces a signal at $\pm 60^\circ$ to the vertical each with 2400 wires also spaced 3 mm apart. Each plane has a spacing also of 3 mm from eachother. The first two planes are the induction planes and the last is the collection. The 270 V/cm electric field of the TPC is created using 64 stainless steel tubes shaped into rectangles around the TPC and held in place by G10 to form a field cage. The cathode is charged at a high voltage of -70 kV and this voltage is stepped down across the field cage tubes using a voltage divider chain with an equivalent resistance of $240\text{ M}\Omega$ between the tubes. The field cage tubes are separated by 4 cm from center to center. The electron drift distance is 2.5 m in the x direction with a drift time of 2.3 ms. Maintaining high charge yield is done by continuously recirculating and purifying the argon. The purity is monitored using MicroBooNE's light collection system. Another use of the light collection system is initial timing and drift coordinate of the interaction.

MicroBooNE's light collection system is a crucial part for 3D reconstruction of all particle interactions in the LArTPC. The initial interaction time, t_0 , and initial drift coordinate, x_0 , are not known from the TPC alone. For beam events, the accelerator clock is used to determine t_0 of the interaction and the x_0 can be inferred using drift time. Non-beam events, however, do not have this capability, which is why scintillation light from an interaction is used. The $\nu - Ar$ interaction produces scintillation light which is collected by photomultiplier tubes (PMTs) which allows the exact time, t_0 of the neutrino interaction to be determined. The scintillation light created propagates within nanoseconds to the light collection system compared to the milliseconds it takes the ionized electrons from the interaction to reach the anode wire planes. Therefore we can precisely know where along the drift direction the particle interaction first took place. The scintillation light is also localized, so combining the PMT information with the wire plane information allows for cosmic background rejection happening outside the beam timing window.

The light collection system is made up of 32 Hamamatsu R5912-02mod cryogenic PMTs with a diameter of 8-inches. The PMTs are located behind the 3 wire anode planes and provides 0.85% photocathode coverage. Each PMT has an acrylic plate mounted in front of it that is coated with a wave-length shifting material called TPB.

721 The acrylic plates take in the scintillation light, at 128 nm, and re-emits it visible
722 wavelengths visible to the PMTs, with a peak at 425 nm.

723 Both the light collection system and the TPC create analog signal that is read out and
724 digitized by the electronics system. The process requires amplification and shaping of
725 the signal which then goes to the data acquisition (DAQ) software for writing of the
726 digitized data to disk. The anode plane wires are connected to detector specific circuit
727 boards (ASICS) that are submerged and operate inside the liquid argon volume. These
728 ASICS send amplified signal to 11 feed-throughs where further amplification of the
729 signal happens outside the cryostat. The signal is received by custom LArTPC readout
730 modules distributed over nine readout crates which do the digitization. The TPC wires
731 are digitized at 16 MHz then downsampled to 2 MHz. The TPC system reads out 4
732 frames of wire signal data per event, 1 frame before a trigger and 2 frames after the
733 triggered frame. The four frames allows for identification of a neutrino interaction as
734 well as cosmic background rejection. The process of digitization is similar for the light
735 collection system. Each PMT signal undergoes a shaping with a 60 ns peaking time
736 for digitization of multiple samples. The digitization occurs at 64 MHz but are not
737 read out continuously during the TPC readout time. Only shaped PMT signal samples
738 above a small threshold are read out and saved. Both the TPC and PMT readouts are
739 initiated via triggers on a separate trigger board located in a warm electronics crate.
740 The timing trigger is created by a timing signal from the BNB accelerator which is
741 shaped and sent to the trigger board. The PMT trigger is generated when the PMT
742 signal multiplicity is greater than 1 and the summed PMT pulse-height is more than 2
743 photo-electrons summed up over all PMT channels. When the trigger board gets both
744 a timing trigger and a PMT trigger in coincidence, at BNB trigger is then generated by
745 the board. This signal is then passed to all readout crates initiating the readout of data.
746 The data is then sent to the DAQ software which then saves the data to disk into one
747 event memory.

748 3.3 MicroBooNE's Physics Goals

749 3.3.1 The low-energy excess

750 The primary goal of the MicroBooNE experiment is to study and investigate the low-
751 energy excess seen in MiniBooNE 3.1. MicroBooNE has the capability of confirming or

denying this excess as electrons or photons due to the detector being in the same beam, having a similar baseline, and lastly the detector being able to clearly distinguish between electrons and photons. LArTPCs use the topology of events as well as energy loss near the vertex to differentiate between single e^- tracks and photon-induced induced pair production $\gamma \rightarrow e^+ e^-$, which wasn't possible in MiniBooNE, a Cherenkov detector. This technique has been shown in the ArogoNeuT detector [?] and a side by side comparison of both event types in a LArTPC can be seen in figure ?? . An excess in electrons would point towards new oscillation physics beyond the standard model, while photons would be within the standard model. MicroBooNE will observe a $4-5\sigma$ signal.

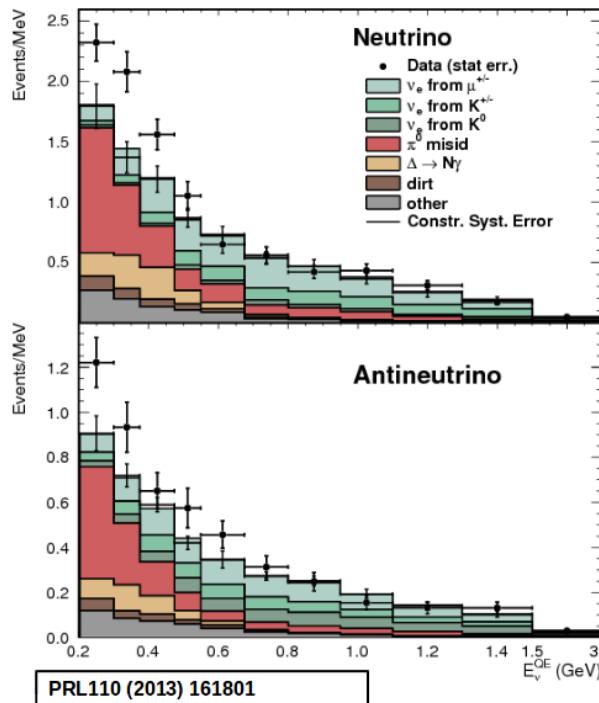

Figure 3.1: Low Energy excess seen in MiniBooNE

3.3.2 Cross sections

MicroBooNE's neutrino cross-section program will be the first $\nu - Ar$ cross-section in the 1 GeV energy range and one of only a few cross-section measurements of $\nu - Ar$ in the world. MicroBooNE is also the first liquid argon detector to collect the highest statistics sample of neutrino interactions. Investigating final-state-interactions in the 1GeV energy range provides information about short range nuclear correlations that affect the interpretations of neutrino oscillation experiment data.

769 One of the cross-section measurements MicroBooNE can make is an inclusive
 770 charged-current cross-section measurement (referred to as CC-inclusive). CC-inclusive
 771 events consist of a neutrino exchanging a W^\pm boson with an argon atom, producing a
 772 charged lepton and any number of other final state particles. In MicroBooNE's case, a
 773 CC-inclusive event will mostly have a defining muon track coming out of the vertex
 774 due to our neutrinos being predominately ν_μ s. A cross-section measurement is the
 775 energy dependent probability of $\nu - Ar$ interaction in the detector. Cross-sections
 776 however are independent of the intensity or focus of the particle beam so they can
 777 be compared among different experiments. A background for a CC-inclusive cross-
 778 section measurement are the neutral-current events that contain a pion. It is possible
 779 to have a neutral current interaction with a $\pi + p$ event signature that looks like a
 780 charged current $\mu + p$ event. Reconstruction tools implemented to date don't efficiently
 781 separate muons from pions. A common way to separate these two particles species is
 782 to implement a track length cut. On average, muons tend to have longer track lengths
 783 in LArTPCs so by requiring that the hypothesized lepton be above a threshold track
 784 length, it is possible to increase signal to background.

785 3.3.3 Liquid argon detector development

786 The last physics goal for the MicroBooNE collaboration is to provide important infor-
 787 mation regarding LArTPC technology. Being the first in large scare LArTPCs in the US,
 788 MicroBooNE will be albe to provide improvements to High Voltage (HV) distribution,
 789 Noise Characterization [?], and Michel Electron Reconstruction [8].

790 3.4 The Booster Neutrino Beam

791 The MicroBooNE detector is stationed at Fermi National Accelerator Laboratory
 792 (FNAL) where it receives neutrinos from both the Booster Neutrino Beam (BNB)
 793 and Neutrinos from the Main Injector (NuMI) beams. MicroBooNE is on-axis for the
 794 BNB and off-axis by 135 mrad for NuMI. For the purpose of this analysis, only data
 795 from the BNB was used. This section will discuss how neutrinos are created using the
 796 BNB. How these neutrinos are produced as well as their flux through the MicroBooNE
 797 detector is necessary for any analysis because of the systematic uncertainties the beam

798 introduces to a measurement. An aerial view of fermilab as well as the BNB is shown
 799 in figure 3.2

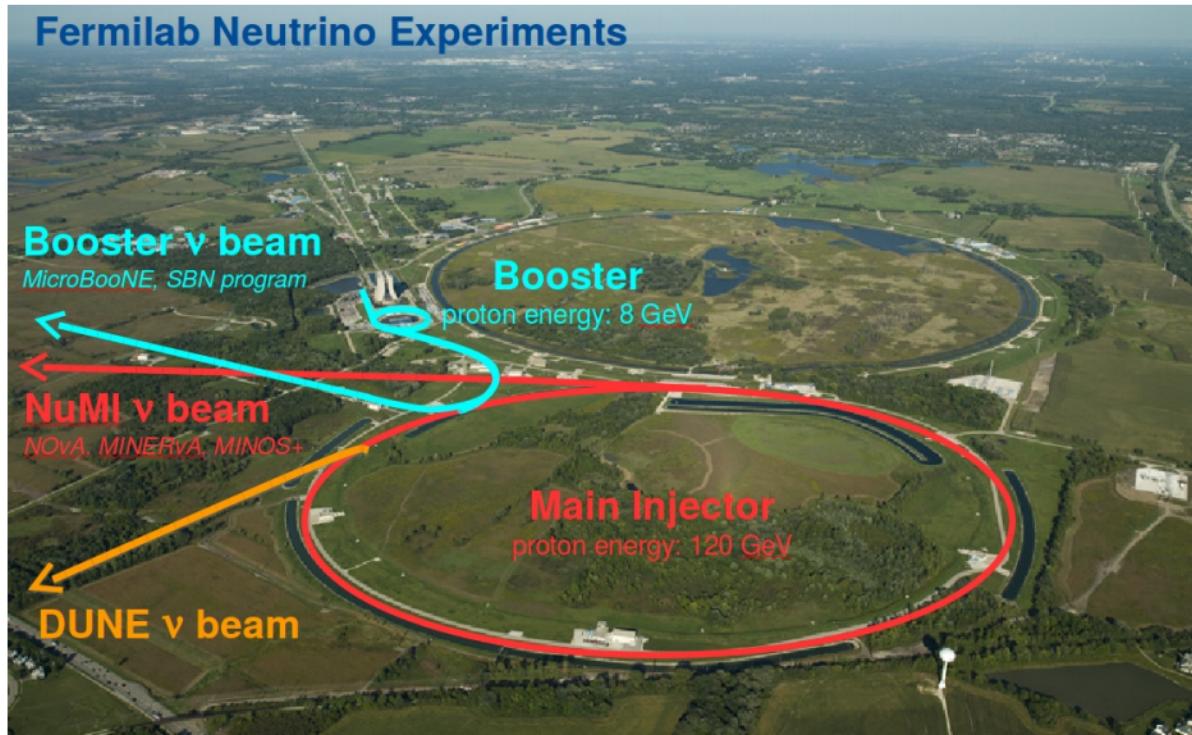

Figure 3.2: Arial view of the Main Injector and the Booster Neutrino Beam at Fermilab

800 3.4.1 Creating the Booster Neutrino Beam

801 The BNB is a very pure ν_μ beam, with only 0.6% contamination from ν_e s. The energy
 802 also peaks around 700 MeV which is desired based on the probability of oscillation
 803 equation which depends on the the value of L/E , where L is the distance of the
 804 detector from the neutrino beam and E is the energy of the neutrino beam. L/E was
 805 chosen to increase the probability of seeing neutrino oscillations in the MiniBooNE
 806 Low Energy Excess (LEE) range based on the probability of oscillation equation, which
 807 is $P_{\nu_\mu \rightarrow \nu_e}(L, E) = \sin^2 2\theta \sin^2 \left(1.27 \Delta m^2 \frac{L}{E} \right)$. The BNB collides 8.9 GeV/c momentum
 808 protons from the FNAL booster synchrotron into a beryllium target which produces a
 809 high flux of neutrinos. The protons originate from H^2 gas molecules that are turned
 810 into H^- ions by a Cockcroft-Walton generator shown in figure ???. The H^- initially are
 811 accelerated to 1MeV kinetic energy and are then passed to a linear accelerator using
 812 alternating electromagnetic fields to increase their energy to 400MeV. The ions are
 813 stripped of electrons by passing them through a carbon foil. The protons are bunched

814 into beam spills which contain $4 * 10^{12}$ protons in a $1.6 \mu\text{s}$ time window per spill. It's
815 at this point that the protons are directed towards the beryllium target. The amount
816 of protons directed towards the target (POT) is measured by two toroids upstream of
817 the target with an error of 2%. Beam intensity, timing, width, position, and direction
818 are monitored by beam position monitors, multi-wire chamber and resistive monitors.
819 The beryllium target is 71.1 cm long, 1.7 proton interaction lengths, and is 0.51 cm in
820 radius. The target is located inside a larger focusing electromagnet called the horn.
821 The horn is an aluminum alloy pulsed toroidal electromagnet. The pulsed current
822 peaks at 170 kA with a time-width of $143 \mu\text{s}$ which coincides with the protons arriving
823 on the target. The current flows from the inner conductor to the outer conductor
824 with a maximum magnetic field of 1.5 Tesla. The magnetic field focuses the charged
825 secondary particles produced by the p-Be interactions. The direction of current can be
826 switched to change the polarity of the secondary particles being focused creating a
827 beam of either primarily neutrinos, with positively charged secondary particles, or
828 antineutrinos.

829 Further down the beamline is a concrete collimator which absorbs particles not
830 necessary to the neutrino flux. The collimator is 214 cm long and 30 cm in radius.
831 After the collimator comes a 45 meter long, 1 meter radius, air-filled cylindrical decay
832 region which then ends in a beam-stop made of steel and concrete. The beam-stop
833 contains an array of gas proportional counters to detect muons. The BNB is shown in
834 figure 3.3.

835 **3.5 Event Reconstruction**

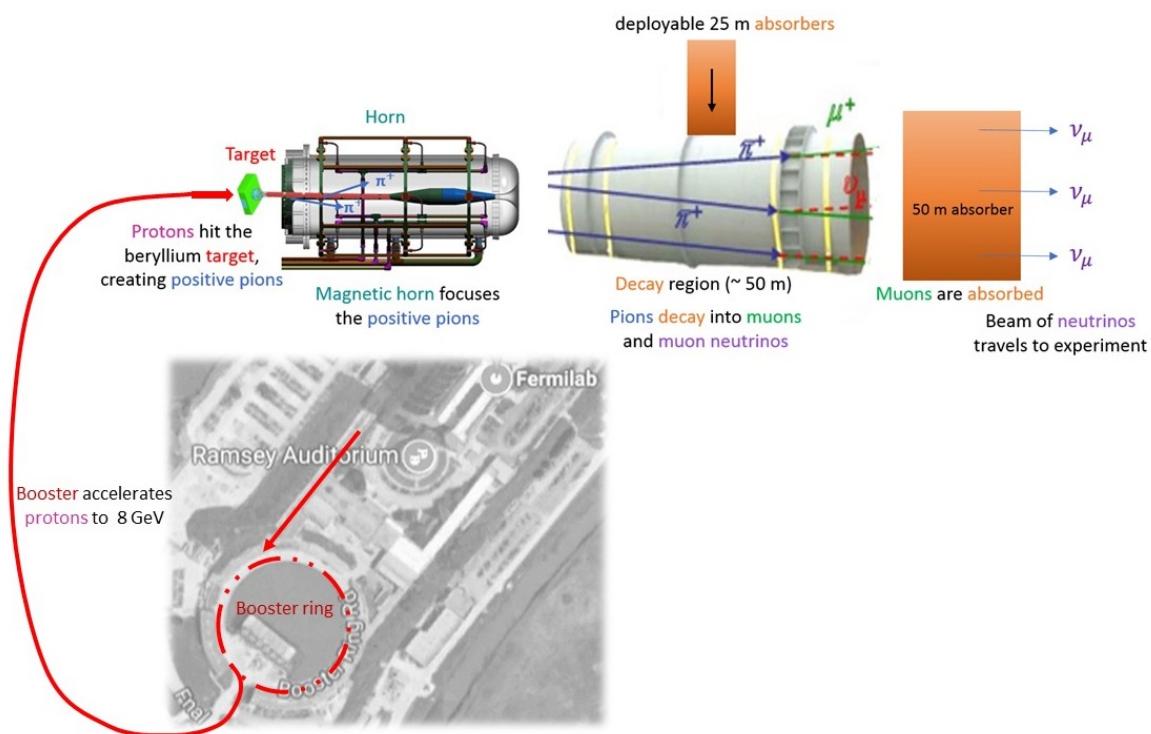

Figure 3.3: Aerial view of the Main Injector and the Booster Neutrino Beam at Fermilab

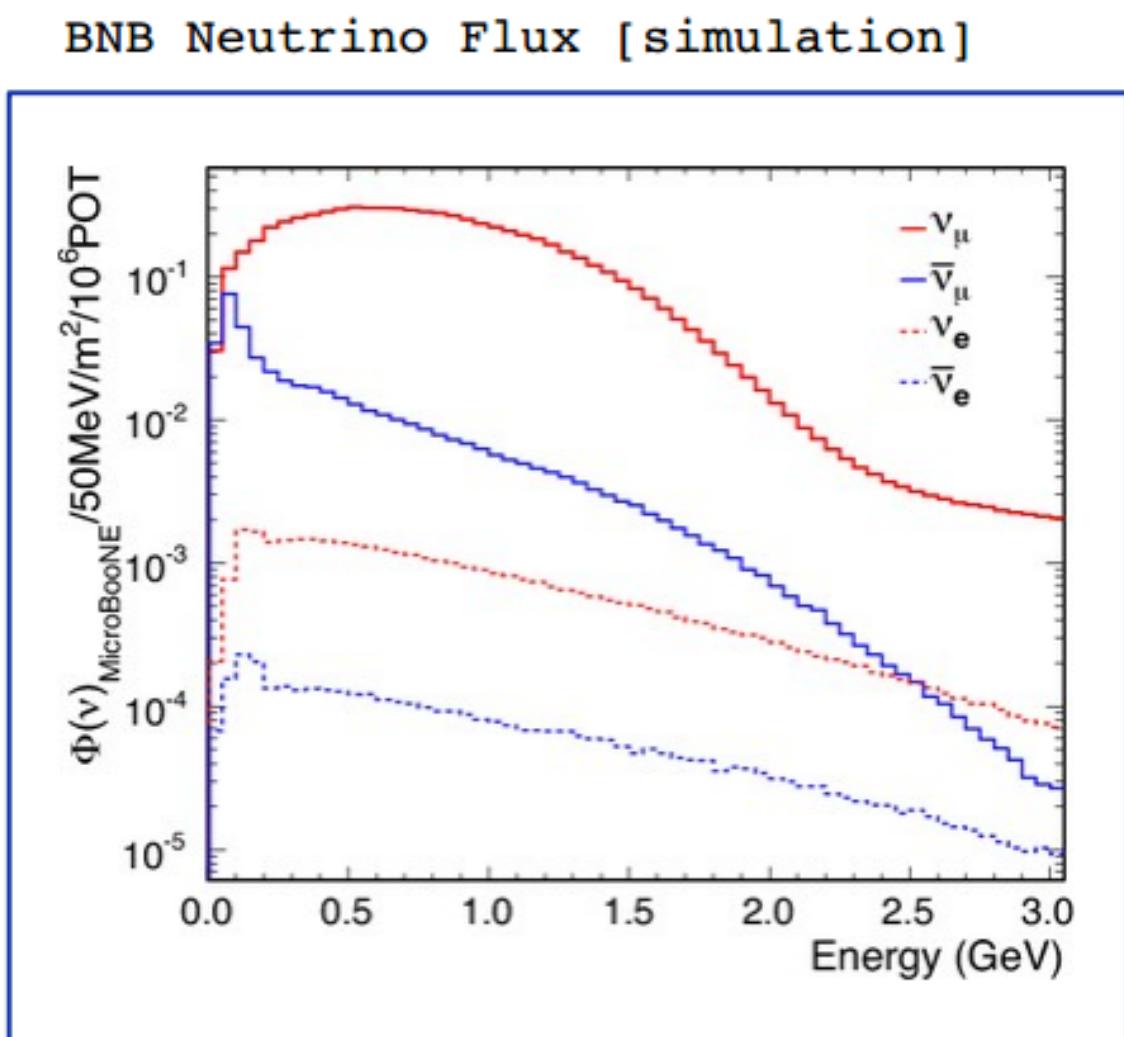

Figure 3.4: Energy spectrum of the Booster Neutrino Beam at Fermi National Laboratories

⁸³⁶ **Chapter 4**

⁸³⁷ **Neutrino Identification: Finding
838 MicroBooNE's first Neutrinos**

⁸³⁹ The goal of the Neutrino Identification analysis was to positively identify BNB neutrino
⁸⁴⁰ interactions in the MicroBooNE detector collected during the first days of running.
⁸⁴¹ Neutrino event candidates were identified in part by using a cut on detected flash of
⁸⁴² scintillation light during the $1.6 \mu\text{s}$ beam-spill length of the BNB as well as identifying
⁸⁴³ reconstructed object from the TPC that are neutrino like. After this selection, 2D
⁸⁴⁴ and 3D event displays were used for verification of the selection performance. This
⁸⁴⁵ selection was targeted to reduce the ratio of neutrino events to cosmic-only events from
⁸⁴⁶ the initial 1 neutrino to 675 cosmics to a ratio of 1 to 0.5 or better which is equivalent to
⁸⁴⁷ a background reduction by a factor of 1000 or more. These selected events were used
⁸⁴⁸ for MicroBooNE's public displays of neutrino interactions. A clearly visible neutrino
⁸⁴⁹ interaction with an identifiable vertex and at least 2 tracks originating from the vertex
⁸⁵⁰ was what the analysis focused on. This analysis wasn't optimized for high purity
⁸⁵¹ or efficiency, but rather for very distinguishable neutrino interactions that could be
⁸⁵² identified by the public.

⁸⁵³ **4.1 Flash Finding**

⁸⁵⁴ Flash finding is the first step used in finding neutrino interactions. This section will
⁸⁵⁵ detail how optical information is reconstructed as well as analysis scripts and event
⁸⁵⁶ filters were used.

857 **4.1.1 Flash Reconstruction**

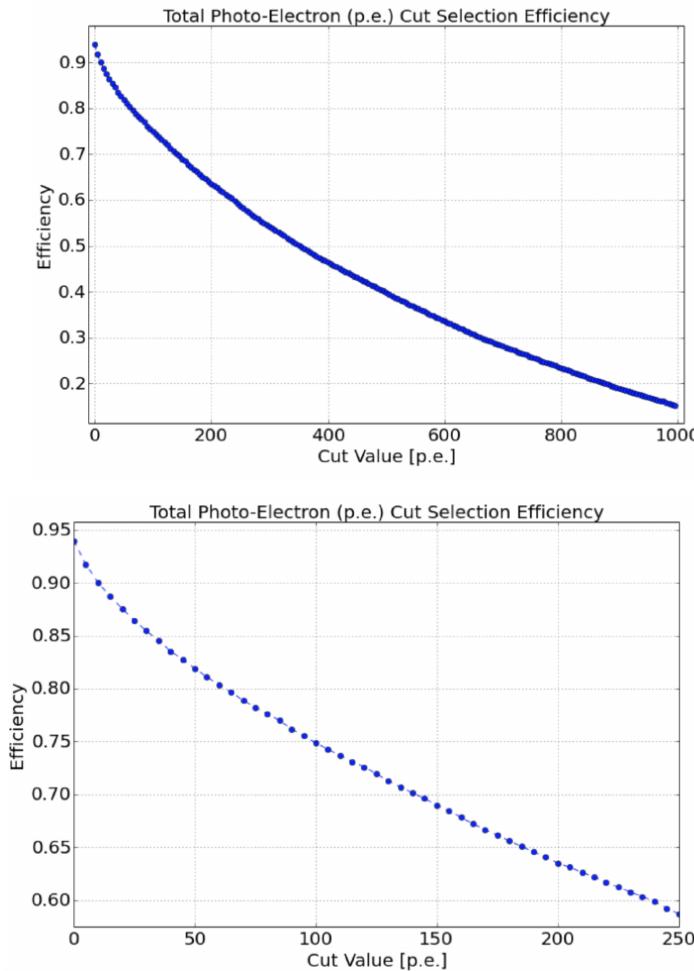

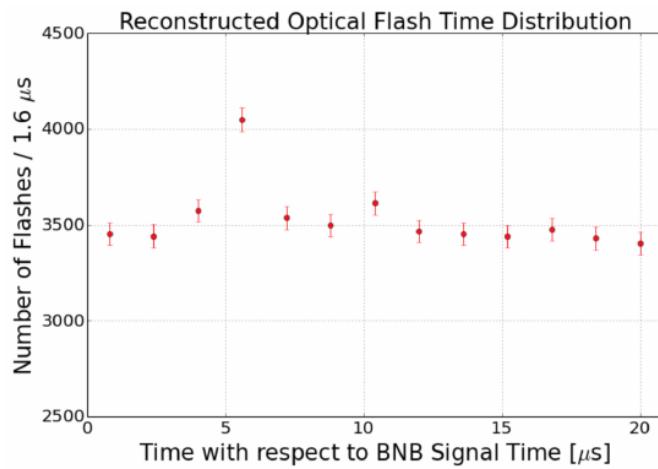

Figure 4.1: Efficiency for selecting beam events as a function of minimum total PE cut for all PE cuts as well as zoomed into interesting region.

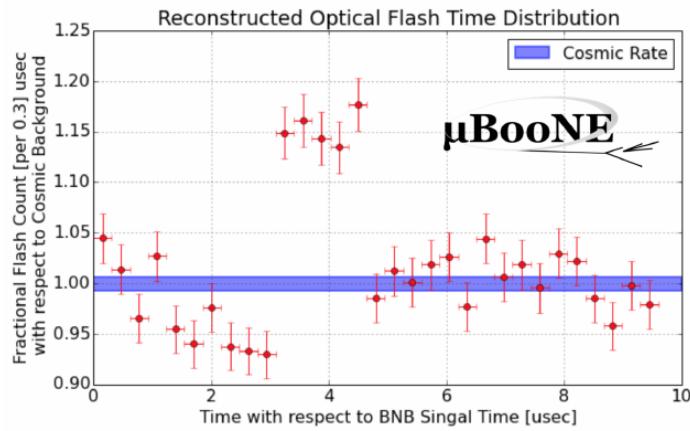

858 A flash is described as a collection of light seen at the same time within the detector.
859 They are then reconstructed by identifying signal from the PMTs above a specific
860 photoelectron (PE) threshold. These signals are called optical hits. Optical hits from
861 all the PMTs are then accumulated into $1\text{ }\mu\text{s}$ bins of time. If a specific bin is above a
862 set PE threshold, then the optical hits that overlap in time are the labeled as the hits
863 from the flash. All flash reconstructed properties like average time and x/y positions
864 are then found via the flash labeled optical hits. The total size of the flash is found by
865 summing up the total number of photoelectrons from all PMTs. Neutrino interactions
866 and cosmic muons will have a larger flash size compared to noise and other low-energy
867 backgrounds, therefore a total PE cut is used to reject these backgrounds. A total PE

⁸⁶⁸ cut of 50 PE was deemed sufficient for this analysis. Figure 4.1 show the total PE
⁸⁶⁹ versus the selection efficency of selecting neutrino beam events.

⁸⁷⁰ **4.1.2 Beam Timing**

(a) Predicted distribution of flash times with respect to trigger time for 1 day of data taking at nominal rate and intensity

(b) Measured distribution of flash times with a 50 PE threshold cut, with respect to trigger time. Shown as a ratio to the expected cosmic rate from off-beam data. A clear excess from neutrinos is visible between 3- 5 μ s after the trigger time.

⁸⁷¹ It is necessary to get the specific time from flashes if one uses flashes to filter out
⁸⁷² neutrino interactions coincident with the neutrino beam spill period and background.
⁸⁷³ Before a filter can be applied, an understanding of the timing of the trigger and PMT

readout with respect to the arrival of neutrinos from the BNB. To do this, a $1.6 \mu\text{s}$ window near the expected beamtime was created and verified by finding that the number of flashes was significantly above the cosmic-ray background flashes. Beam data during the first week of running, October 16th 2016 through October 22nd 2016 and were used for a timing measurement. The total POT uses corresponds to roughly 24 hours of data taking at nominal intensity ($4 \times 10^{12} \text{ ppp}$) and a 5 Hz repetition rate. Figure 4.2a shows size of the expected neutrino signal in time using Monte Carlo predictions and figure 4.2b shows the neutrino signal in data. The intensity in data is lower, however there can still be seen a significant excess above data.

4.1.3 Event Rates

Applying a 50 PE threshold cut inside a $1.6 \mu\text{s}$ window reduces the cosmic-ray passing rate to 0.8%. With a 5 Hz beam rate, this corresponds to 135 cosmics passing per hour. The neutrino passing rate for this filter is about 22 events per hour. To further increase the neutrino to cosmic ratio, TPC topology cuts were implemented and will be discussed in the following section.

4.2 TPC Topology Selection

In order to further reduce the background of cosmic events, two independent selection streams using TPC wire data reconstruction was implemented. The first using 2D reconstructed clusters, and the second using 3D reconstructed tracks. Both streams look for neutrino interactions in the active TPC volume which are identifiable by two or more tracks originating from the same vertex.

Both 2D and 3D channels were optimized using monte carlo simulation which used a 128 kV cathode voltage. Passing rates were calculated using a 0.008 efficiency factor for cosmic events passing to simulate the flash finding described in section 4.1. This efficiency factor was an overestimation and was just used to get a general feel of what signal and background rates we would actually see in data.

900 4.2.1 Cosmic Tagging

901 The first step in TPC selection was based on the geometry of cosmic tracks in an event.
902 The cosmic ray muon geometry tagger runs on 3D tracks and assigns a score to each
903 reconstructed track on the likeliness of the track originating from a cosmic. The cosmic
904 scores are detailed below:

- 905 • 1: The track is tagged as entering or exiting the TPC
- 906 • 0.95: The track is a delta ray associated with a tagged track
- 907 • 0.5: The track is either entering or exiting, but not both
- 908 • 0.4: The track is entering or exiting through the Z boundary
- 909 • 0: The track isn't tagged

910 Clusters are assigned either a 0 or 1, 1 being a cosmic. In simulation, 90% of cosmics
911 are tagged as cosmics. These tracks are no longer considered when looking for a
912 neutrino topology. Requiring that the tracks be contained in turn affects the neutrino
913 efficiency by 20%. The algorithm checks that each track is contained within a boundary
914 region of 10 cm from all sides of the TPC. This boundary region was optimized via
915 handscanning of experimental data.

916 As can be expected, cosmic tagging is more efficient in the 3D channel (tracks) than
917 the 2D channel (clusters) because the reconstructed tracks can use the full 3D position
918 information of the entering and exiting points while the 2D channel mainly use the
919 reconstructed x position of the cluster which is associated to timing.

920 Cosmic tagging uses timing information to reject tracks and clusters that are outside
921 of drift window. The drift window for 128 kV is 1.6 μ s while for 70 kV, the actual
922 voltage MicroBooNE is running at, is 2.3 μ s. Due to this variation between simulation
923 and data, we expect to see $2.3/1.6 = 1.44$ times more cosmic induced tracks or clusters
924 in the drift window.

925 4.2.2 2D Cluster Selection

926 This selection was spearheaded by myself and Katherine Woodruff. After looking at
927 experimental cosmics data, 2D clustering performs well, while 3D track reconstruction
928 is affected by more variations in simulation, for example noise filters. This was the

929 motivation for having a selection only on 2D clusters in the collection (Y) plane. As
 930 stated previously, the goal of this analysis was to find identifiable neutrino interactions
 931 for use in public event displays, in future analyses, the 3D track reconstruction has
 932 been modified to further increase the tracking efficiency and has more information
 933 than just the clusters. For this analysis, however, 2D cluster information was sufficient
 934 enough for neutrino selection.

935 **Primary Cuts**

936 The first cuts were used to select which clusters to consider. First the clusters must
 937 have at least ten hits on the collection plane and have a cosmic tagging score < 0.4.
 938 Only events that have at least two clusters that satisfy these primary cuts continue on.

939 After the initial cosmic tagging is applied, the following cuts are used to further
 940 separate identifiable neutrinos from background cosmics.

941 The next cut was to remove long, vertical clusters. This was applied after seeing
 942 that most cosmic induced clusters passing were long with high angles, while neutrino
 943 induced clusters were mainly forward going. We required a good cluster to either
 944 have a projected start angle less than 30 degrees from the z axis or be less than 200
 945 wires long. The length cut was added to make sure we don't cut any short high angle
 946 clusters that can correspond with a proton, or other highly ionizing particle associated
 947 with a long muon cluster. The 200 wire cut roughly equates to 0.6 m in the z direction,
 948 with a 3 mm wire pitch. Also, the projected angle is defined by $\tan \alpha = \Delta T / \Delta W$ where
 949 T is the time ticks and W is the wires.

950 The last cut requires the clusters to be either 30 time ticks or 30 wires. This cut was
 951 applied to reduce small delta rays associated with a cosmic without removing proton
 952 clusters associated with a long muon cluster, which saves ideal neutrino events that
 953 have both a long minimum ionizing muon like cluster and a short highly ionizing
 954 proton like cluster.

955 **Secondary Cuts**

956 The secondary cuts look to match long, low-angle clusters with short, high-charge
 957 clusters. Only clusters that have passed previous cuts are used. First clusters with
 958 length greater than 100 wires are chosen, which is approximately 0.3 m in the z

Cluster set	No Cuts	Primary Cuts	Secondary Cuts
Neutrinos only	570	303	32
Cosmics only (no flash)	308,016	291,879	602
Cosmics only (w/ flash)	2464	2335	5
Neutrinos/Cosmics	0.23	0.13	6.4

Table 4.1: Passing rates for 2D cluster cuts for neutrino on MC set and a cosmic only MC set. First column shows event rates with no cuts applied to both sets. Columns two and three show event rates after primary and secondary cuts are applied. Line three shows the second line scaled with the flash finding factor of 0.008. All events are normalized to per day assuming we are running at 5 Hz.

959 direction. Then we search for any cluster that is within approximately 3 cm (10 wires
 960 and 30 time ticks) away from the low-z end of the long cluster. This cluster must also
 961 be shorter than the first. In our reconstruction, the start and end point of a cluster can
 962 be swapped so both ends of the short cluster are compared to the long cluster.

963 Now that there is a vertex match, cuts based on charge and projected opening angle
 964 are implemented. We require the short cluster to have a higher start charge than the
 965 long cluster or the long cluster be longer than 500 wires. Start charge is defined as
 966 the charge on the first wire in ADC counts. The projected opening angle must also
 967 be between 11 and 90 degrees. This last cut is intended to remove clusters that are
 968 entirely overlapping or are part of the same long track. The resulting neutrino/cosmic
 969 event rate per day is shown in table 4.1. Figures 4.3 and 4.4 shows the percentages of
 970 clusters that pass each primary and secondary cuts.

971 4.2.3 3D Tracks and vertices Selection

972 The neutrino selection for the 3D channel was based on a reconstructed vertex and
 973 two tracks. All vertices and tracks were looped over that had a cosmic tag score < 0.4
 974 and the distances below were calculated:

- 975 • d : distance between the start points of the two tracks.
- 976 • d_1 : distance between vertex and start of track 1.
- 977 • d_2 : distance between vertex and start of track 2.

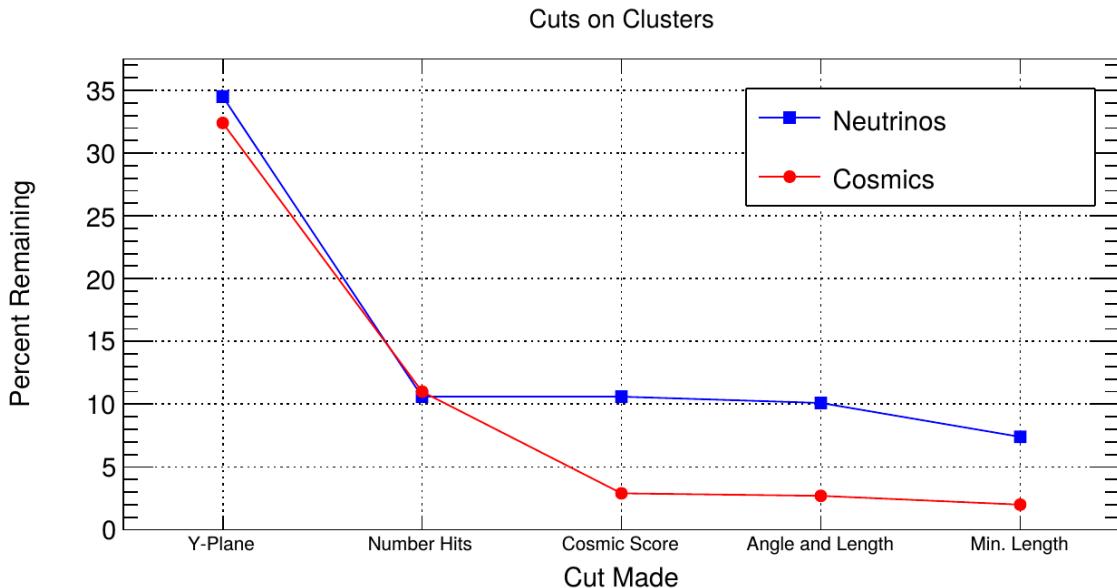

Figure 4.3: Percent of good clusters remaining for neutrinos and cosmics after the primary cuts were applied. This is relative to total number of initial clusters.

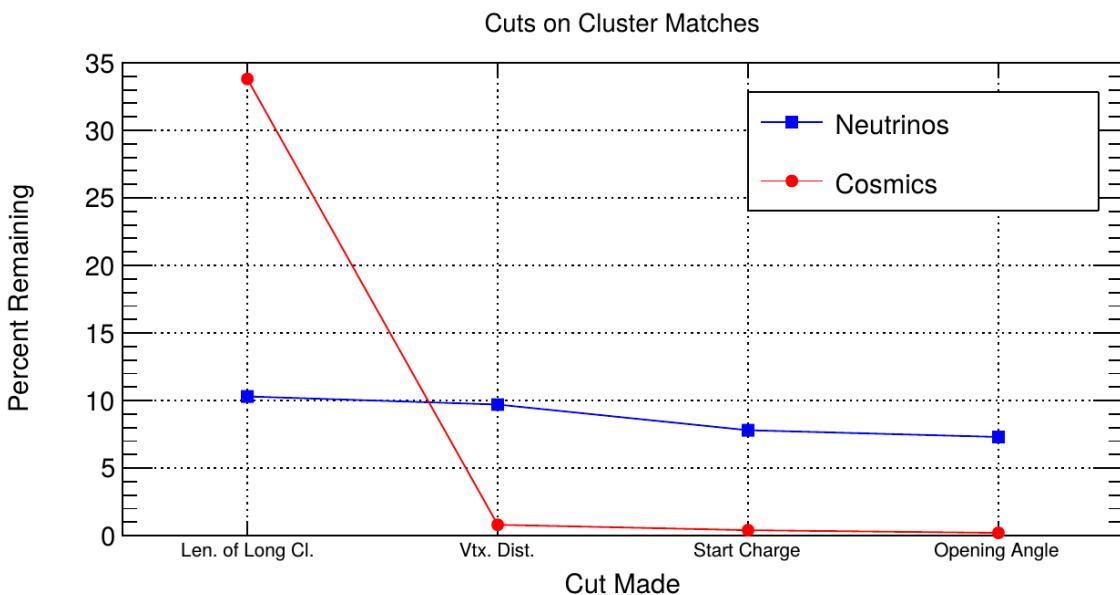

Figure 4.4: Percent matched cluster pairs remaining for neutrinos and cosmics after secondary cuts applied. This is relative to the number of events that contain clusters which pass the primary cuts.

978 The maximum distance of all three is then selected as the important characteristic per
979 trio. The best trio is the one that has the smallest maximum distance. The $\min(\max_d)$
980 for all trios in an event were plotted for BNB neutrino events and for cosmics to
981 find the best cut value for each tracking algorithm. The distribution of $\min(\max_{d,i})$
982 is smaller for neutrinos than for cosmics. The cut values for different tracking and
983 clustering algorithms are shown below. These cut values were chosen to minimize the
984 cosmic background to 20%.

- 985 • trackkalmanhit with cccluster $\min(\max_{d,i}) < 3$ cm.
- 986 • trackkalmanhit with pandoraNu $\min(\max_{d,i}) < 4.5$ cm.
- 987 • pandoraNu with cccluster $\min(\max_{d,i}) < 5$ cm.

988 4.2.4 TPC Updates

989 After doing a visual hand-scanning of the first beam data processed with the filters
990 detailed above, the events passing had a larger contamination of background than
991 expected. This was mainly in part due to the reconstruction performing better on
992 simulation than on data. Due to this, additional cuts on both streams needed to be
993 implemented in order to increase signal/background ratio. These cuts were added on
994 top of the filters described above and further reduce the event count.

995 2D Filter Updates

996 The main background observed in the 2D filter were Michel events, where the muon
997 and electron formed two connected clusters. These events were rejected by comparing
998 the start and end charge deposition of the long cluster (i.e muon particle). The start
999 charge deposition must be less than the end charge deposition. This cut is implemented
1000 because muons have a higher ionizaiton loss at the end.

1001 3D Filter Updates

1002 It was seen that cosmic tracks can often originate or end at the same point, therefore
1003 faking a signal. Cosmic tracks, however, are mostly vertical. By requiring the angle
1004 of the longer track have a cosine greater than 0.85 with respect to the z-axis as well

₁₀₀₅ as requiring the longer track to have a length greater than 10 cm, we can reduce this
₁₀₀₆ background.

₁₀₀₇ **4.3 Conclusion**

₁₀₀₈ After proccesing these filters in parallel, it was shown that the 3D filter had a higher
₁₀₀₉ purity than the 2D filter because of the higher cosmic rejection being used due to 3D
₁₀₁₀ reconstruction. The 2D filter is blind to track entering/exiting from the top or bottom
₁₀₁₁ of the TPC. Although the 3D filter had a higher purity, the 2D filter was still able to
₁₀₁₂ find identifiable events in data that were used as public event displays. A sample of
₁₀₁₃ event displays are shown in figures ?? and ??.

1014 **Chapter 5**

1015 **CC-Inclusive Cross Section Selection**

1016 **Filter**

1017 The CC-Inclusive cross-section selection I and selection I modified filters used in this
1018 analysis will be described in the following sections below. These filters are an expansion
1019 of the Neutrino ID filter. The work done in this thesis was to further improve these
1020 selections by increasing both efficiency and purity as well as increasing acceptance
1021 without further affecting the kinematic distributions of the selected neutrino events.

1022 MicroBooNE requires fully automated event reconstruction and selection algorithms for use in the many physics measurements being worked on to date due to
1023 the large data rate MicroBooNE receives. Being able to automatically pluck out the
1024 neutrino interaction among a sea of cosmics proved to be challenging but was accomplished.
1025 MicroBooNE has developed two complementary and preliminary selection algorithms to select charged-current $\nu_\mu - Ar$ interactions. Both are fully automated
1026 and cut based. The results of this thesis will focus on selection I and selection I modified
1027 and will focus on further improving these algorithms using Convolutional Neural
1028 Network (CNN) implementations. These selections identify the muon from a neutrino
1029 interaction without biasing towards track multiplicity. To combat cosmic and neutral
1030 current background, the analysis is strongly biased towards forward-going long tracks
1031 which are contained. This limits phase space and reduces acceptance.
1032
1033

1034 5.1 Data and MC Processing Chain

1035 The data used for this analysis were based on hardware and software triggers. Events
1036 used came from the *BNB_INCLUSIVE* and *EXT_BNB_INCLUSIVE* streams and were
1037 used for signal and background. The *BNB_INCLUSIVE* stream is chosen by requiring
1038 that the hardware trigger bit is fired and that the event passed an optical software
1039 trigger within a BNB spill timing window. The *EXT_BNB_INCLUSIVE* stream requires
1040 the EXT hardware trigger to fire as well as pass the same optical software trigger
1041 within a BNB spill size timing window similar to the *BNB_INCLUSIVE*.

1042 The two MC samples used in this analysis and for determining selection efficiencies
1043 and purities were GENIE BNB neutrino interactions with CORSIKA cosmic ray overlay
1044 within the readout window and inTime CORSIKA cosmic rays. The MC samples
1045 generated used *uboonecode v04_36_00* and are based on the following packages:

- 1046 • larsoft v04_36_00
- 1047 • GEANT v04_09_06_p04d
- 1048 • GENIE v02_08_06d
- 1049 • GENIE xsec v02_08_06a
- 1050 • pandora v02_03_0a
- 1051 • CORSIKA v07_4003

1052 Both data and MC samples were processed using the same reconstruction release,
1053 *uboonecode v05_08_00* and the fcl files used for reconstruction are listed below:

- 1054 • MC fcl files
 - 1055 – reco_uboone_mcc7_driver_stage1.fcl
 - 1056 – reco_uboone_mcc7_driver_stage2.fcl
- 1057 • Data fcl files
 - 1058 • reco_uboone_data_Feb2016_driver_stage1.fcl
 - 1059 • reco_uboone_data_Feb2016_driver_stage2.fcl

1060 On top of the hardware and software triggers, the data also had to pass more
1061 criteria to be identified as part of the good run list. The criteria is detailed below.

- **Detector conditions:** the detector has to be in a good operating condition. The detector conditions are read from the slow monitoring database and are required to be within the alarm thresholds. The variables of interest for events passing the good run list criteria include DAQ, PMT, HV, Drift HV, wire bias, electron lifetime and detector power. These conditions need to be met on a run-by-run basis in order to pass the selection.
- **Data quality:** normal and stable behavior for basic reconstruction quantities. These reconstruction variables include average number of tracks, hits, and flashes in each event, the average length of tracks, the average amplitude and area of hits, the average PE and the average spread of each one of these quantities.
- **Beam Conditions:** the BNB must be on and stable and the POT per spill needs to be above the intensity threshold. Beam quality conditions include checking the fraction of proton beam interacting within the target, the horn current, and the intensity of protons per spill. The final sample is $5 * 10^{19}$ and a per-spill intensity of $4 * 10^{12}$
- **Run processed:** the full run must be processed completely without missing subruns or crashes in the data processing.

5.2 Normalization of data and MC

The off-beam sample is used to measure beam unrelated backgrounds. For normalization, one needs the total number of BNB spills (N_{BNB}) and the total number of external triggers. The BNB spills used need to pass the beam quality cuts. The normalization factor is then N_{BNB}/N_{EXT} which is 1.23.

To normalize generated BNB MC events to POT, we used the following:

- $5 * 10^{19} POT = 41524.3$ generated events

where this scaling factor only applies to mcc7 generated events. The inTime cosmic sample is normalized with respect to the open cosmic sample so an understanding of both is necessary. The POT per beam spill for mcc7 BNB samples is $5 * 10^{12}$. To calculate how many spills are necessary to produce a specific POT one would multiply the total POT by the average 1/POT per spill. For a total POT of $5 * 10^{19}$ the amount of spills necessary is $\frac{5*10^{19}}{5*10^{12}} = 1 * 10^7$. This is only one in ~ 241 events therefore each

1092 cosmic event needs to be scaled up by a factor of 240.8 when comparing to BNB
 1093 MC. For inTime cosmics however, two filters are applied to reduce computing and
 1094 processing time and only leave cosmics that will interact within the detector. The
 1095 passing rate after these two filters is 0.02125, therefore the total inTime cosmic scaling
 1096 factor to compare inTime cosmics to BNB is $0.02125 * 240.8 = 5.12$.

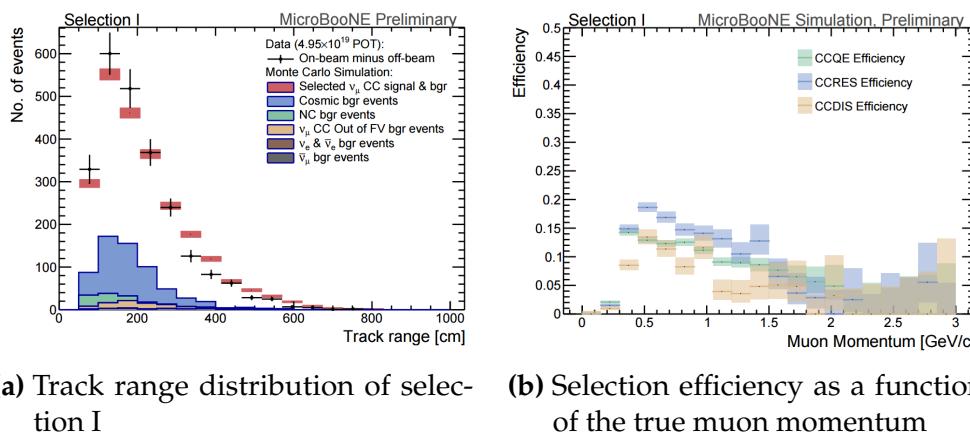

Figure 5.1: 5.1a Track range distribution for selection I. The track range is defined as the 3D distance between the start and end of the muon candidate track. No data is shown below 75 cm due to the track length cut described previously. 5.1b Efficiency of the selected events by process quasi-elastic (QE), resonant (RES), and deep-inelastic (DIS). Statistical uncertainty is shown in the bands and the distributions are a function of true muon momentum. The rise of the efficiency between 0 GeV and 0.5 GeV is due to the minimum track length cut and the decreasing efficiency for higher momentum tracks is caused by the containment requirement.

1097 5.3 Optical Software Trigger and Reconstruction

1098 5.3.1 Software Trigger

1099 Most of the BNB spills from the accelerator do not have a neutrino interaction in
 1100 MicroBooNE. To save computation resources and reduce data-rates, we require a
 1101 burst of light in the light collection system in coincidence with the 1.6 μs beam spill.
 1102 Requiring light activity in coincidence with the beam spill eliminates the vast majority
 1103 of triggers with no neutrino interaction in the detector, however, it doesn't guarantee
 1104 the activity in the detector is a neutrino interaction since a cosmic ray can interact in
 1105 coincidence with the beam spill as well.

1106 To implement this, a software trigger was used on the PMT waveforms to decide
1107 whether or not to keep that event. The software trigger is implemented after the event
1108 builder combines data from the PMTs and triggers into a single event. The software
1109 trigger uses the digitized output of the 32 PMT channels in the light collection system.
1110 Only the waveform region in coincidence with the beam spill is used to search for
1111 possible triggers. For each PMT, a waveform is found by taking the difference of ADC
1112 values is calculated between t and $t + s$. This waveform is then scanned for ADC
1113 values above a threshold X_0 . Once an ADC is above this threshold, a discriminator
1114 window is opened for a fixed number of time ticks (W_0). If the ADC count within this
1115 window W_0 is greater than a second larger threshold X_3 , a final window of width W_3
1116 is opened. The max ADC value within this final window is set as the peak amplitude
1117 for the PMT and then summed across all 32 PMTs and set to the variable PHMAX. The
1118 software trigger places a final cut on the PHMAX variable to decide whether or not
1119 to keep the event. The thresholds were found by the Trigger task force using Monte
1120 Carlo Studies and are as follows:

- 1121 • $X_0 = 5$ ADC
- 1122 • $X_3 = 10$ ADC
- 1123 • $W_0 = 6$ Ticks
- 1124 • $W_3 = 6$ Ticks
- 1125 • PHMAX cut = 130 ADC

1126 5.3.2 Flash Reconstruction

1127 MicroBooNE collects light from each of the 32 PMTs either in a continuous readout
1128 window of $23.4 \mu\text{s}$ activated by a beam gate signal on the trigger board, or in discrimi-
1129 nated pulses of $\sim 1 \mu\text{s}$ duration activated if the ADC count for any PMT goes above 80
1130 ADC count. These two formats are saved as output waveforms and put onto an event.
1131 Additionally, each PMT can provide two output streams, high-gain (~ 20 ADC/PE)
1132 and low-gain (~ 2 ADC/PE) channels. The first step in the reconstruction is to merge
1133 both these channels into a “saturation corrected waveform” which uses information
1134 from the low-gain waveform to correct for saturating high-gain pulses.

1135 The saturation corrected waveform in the continuous readout window is used to
1136 reconstruct optical hits. Each PMT’s waveform is scanned for hits then a threshold

1137 based hit reconstruction algorithm is applied which requires pulses of a minimum
1138 area in order to be reconstructed. Each reconstructed hit is associated to a PMT, a time
1139 in μs , and a PE count.

1140 Once hits are reconstructed for all 32 PMTs, all PMT information is then combined
1141 into optical flashes which represent optical information seen by the PMTs from interac-
1142 tions in the detector. Each flash has information on total light seen per interaction, the
1143 distribution of the light across all 32 PMTs, the flash time with respect to the trigger
1144 time of the flash, and lastly, the spacial information of the flash in Y-Z plane of the
1145 detector. These flashes are reconstructed by requiring that there is a $\sim 1 \mu\text{s}$ coincidence
1146 between the reconstructed hits in all 32 PMTs. The total PE is summed up among
1147 all coincident hits across the PMTs and if the total PE is greater than 2 PE, a flash is
1148 reconstructed. There are also safe guards in place to take care of late scintillation light.

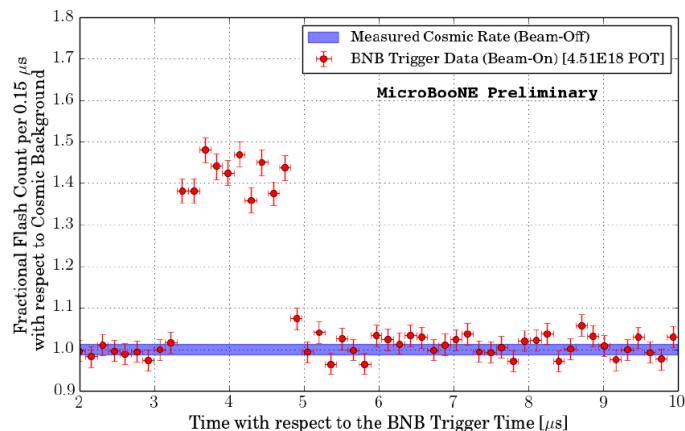

Figure 5.2: Time distribution of reconstructed optical flashes with a PE value of 50 or more for a sample of BNB unbiased triggered events.

1149 Figure 5.2 shows the time distribution of reconstructed optical flashes using the
1150 BNB continuous stream. You can see a clear excess in coincidence with the expected
1151 arrival time of neutrinos. The same flash reconstruction that was used in the cc-
1152 inclusive filter detailed here was used to create this plot in data.

1153 5.3.3 Beam Window

1154 Figure 5.3 shows the distribution of flashes for on-beam, off-beam and various MC
1155 samples. The software trigger has been applied to these samples. The pile-up seen just
1156 after 0 μs is a feature of the flash finding algorithm and consists of low PE flashes and

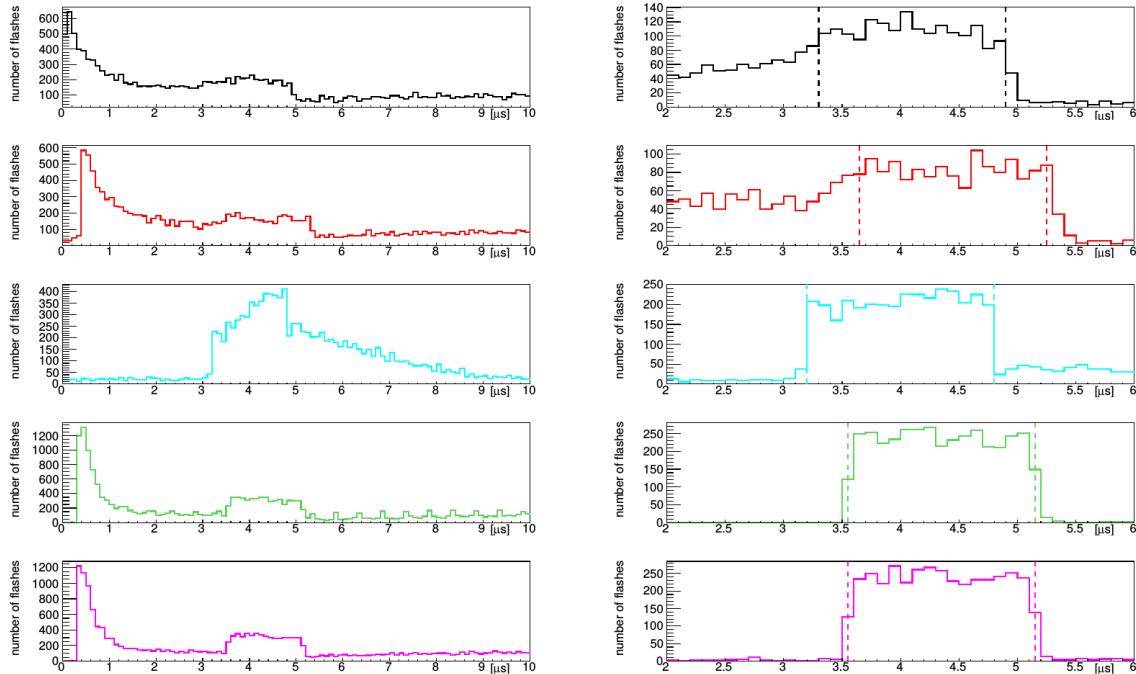

Figure 5.3: Flash time distribution for all flashes (left plot) and flashes $> 20\text{PE}$ (right plot). The different curves are as follows: on-beam data (black), off-beam data (red), CORSIKA inTime MC (light blue), BNB only MC (green), and BNB+Cosmic MC (purple). The dashed vertical lines mark the time window that was chosen for each sample

1157 is removed in the second column of distributions with a low 20 PE threshold cut. The
1158 plots show that the time window for the distributions are shifted a small amount from
1159 each-other. This is caused by different hardware configurations per sample. Using
1160 these distributions, the windows chosen per sample are as follows:

- 1161 • On-Beam: 3.3 to 4.9 μ s
- 1162 • Off-Beam: 3.65 to 5.25 μ s
- 1163 • CORSIKA inTime: 3.2 to 4.8 μ s
- 1164 • BNB only: 3.55 to 5.15 μ s
- 1165 • BNB+Cosmic: 3.55 to 5.15 μ s

1166 Each window has a width of 1.6 μ s.

1167 5.4 TPC Reconstruction

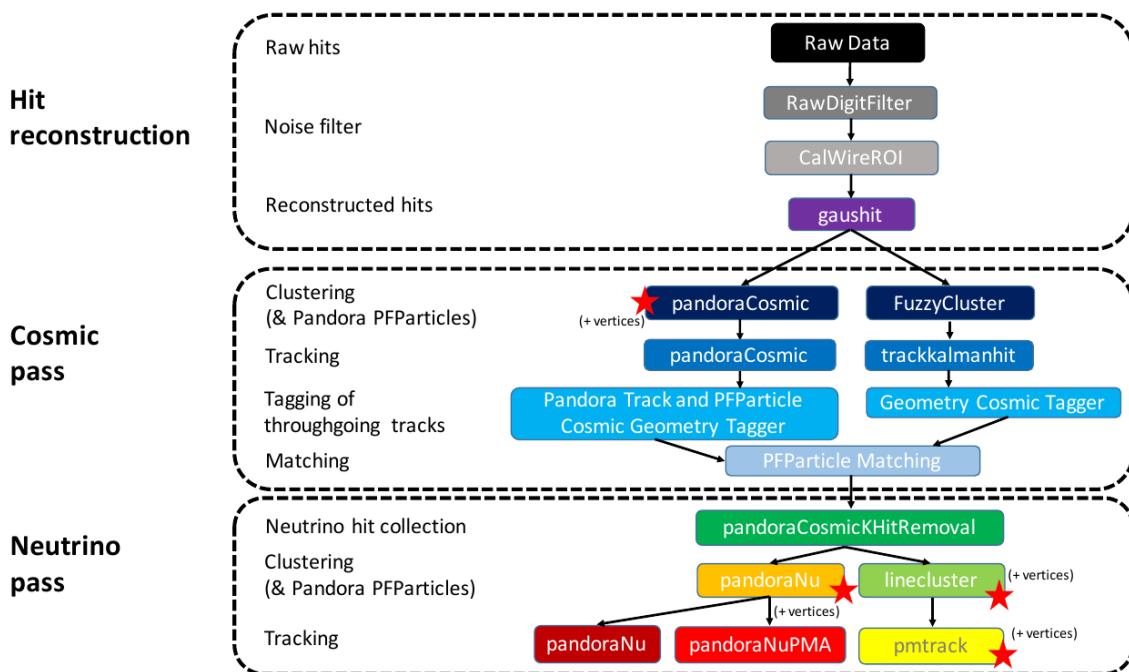

Figure 5.4: Reconstruction chain run on both data and MC. The red stars mean that the algorithm returns reconstructed 3D vertices.

1168 Figure 5.4 summarizes the reconstruction chain applied to both MC and data for
1169 this analysis. After the hit reconstruction, a cosmic pass is applied which removes all
1170 hits associated to through-going tracks. A description of these TPC reconstruction
1171 algorithms will be detailed below.

1172 **5.4.1 Hit Reconstruction**

1173 The waveforms used for hit reconstruction consist of charge deposited on the sense
1174 wire in drift time. The first step in hit reconstruction is to pass the waveforms through
1175 a filtering algorithm to filter out the noise introduced from the electronics. The input
1176 waveforms are also truncated from 9600 time ticks to 6400 time ticks in this first step
1177 to reduce the data footprint of these waveforms.

1178 Once noise filtering is complete, a deconvolution algorithm is applied to the wave-
1179 forms to remove the drift field and electronics response, therefore leaving only the
1180 ionized electrons kicked off the argon atoms by an incident track. During this process,
1181 Region of Interests (ROI) are identified and cut out of the waveforms to further reduce
1182 the data volume.

1183 The hit finding algorithm then finds candidate peaks in these ROI's and fits the
1184 peaks to Gaussian curves. These Gaussian shaped peaks are now called hits and
1185 represent the charge deposition on a wire by the incoming track. These hit objects
1186 have a peak time and width and are the basic object input to further algorithms down
1187 the reconstruction chain.

1188 **5.4.2 Clustering**

1189 There are multiple clustering algorithms used in this analysis. The main purpose of all
1190 the clustering algorithms is to associate hits together in 2D space to create objects like
1191 tracks, vertices and showers. For the fuzzy cluster algorithm, three steps are used to
1192 achieve this. The first step is to associate hits to each-other using a fuzzy clustering
1193 algorithm which gives each hit a degree of belonging to the cluster. Second, a Hough
1194 transform is used to find hits associated to candidate tracks and showers within each
1195 of the clusters found in the first step. The last step merges smaller candidate tracks
1196 and showers into large clusters. The last step also associates unclustered hits into

1197 nearby objects which helps shower reconstruction. The result is a set of clusters made
1198 up of associate hits that represent tracks or showers per plane.

1199 The pandora algorithm utilizes it's own clustering algorithm and will be detailed
1200 in the next section. The last clustering algorithm is called linecluster. The linecluster
1201 algorithm reconstructs 2D linear clusters per plane by fitting a line onto nearby hits
1202 which is then extrapolated to neighboring wires. 2D vertices are found per plane by
1203 using the intersection points of the ends of nearby clusters. These 2D vertices are then
1204 matched in time across all three planes to get a 3D vertex in space.

1205 5.4.3 Pandora

1206 5.4.4 Trackkalmanhit

1207 The trackkalmanhit algorithm takes 2D clusters returned from the fuzzy cluster algo-
1208 rithm and outputs track objects. There are no hierarchy structure as it is in pandora,
1209 each track is independent. There also is no vertex reconstruction with this algorithm
1210 as well.

1211 5.4.5 Cosmic Hit Removal

1212 The Pandora algorithm is applied to the events twice, the first to remove downward
1213 going tracks primarily from cosmic ray muon like particles. The second pass only runs
1214 on a subset of hits that aren't associated with cosmic ray muon tracks.

1215 After the first pass, the output of PFParticle hierarchy is then passed to a cosmic
1216 ray tagger to look through all hits to determine start and end points. If the start or
1217 end point trajectories are consistent with entering or exiting the TPC, then these hits
1218 are removed from the second pass. Hits are considered entering or exiting the TPC
1219 if the drift time are outside of the neutrino drift window or outside of the fiducial
1220 volume of the TPC. The fiducial volume was based on a montecarlo study and is 20
1221 cm from the top or bottom of the TPC and 10 cm from the TPC ends. Hits associated
1222 with candidate cosmic ray tracks are removed from the input hit collection and the
1223 remaining hits are passed to the neutrino optimized pass of Pandora.

1224 5.4.6 Projection Matching Algorithm

1225 The projection matching algorithm (PMA) was inherited from ICARUS and has been
1226 implemented in LArSoft. PMA differs from traditional LArSoft 3D reconstruction
1227 algorithms. Most 3D reconstruction attempts to match 2D objects from all three planes
1228 by drift time, while the PMA algorithm projects a track hypothesis on each plane
1229 then the distance between this projection and the hits on each plane is minimized
1230 simultaneously. More information can be found in [?].

1231 5.5 Event Selection

1232 The first requirement for selecting ν_μ CC events is that the event has at least one
1233 scintillation light flash in the beam trigger window with more than 50 PE on all PMTs
1234 combined. From the flashes that pass, the most intense is chosen and considered to be
1235 originating from a neutrino interaction and will be the only flash used in further cuts.

1236 Vertices are then required to have at least one reconstructed track start or endpoint
1237 within a 5 cm radius. Showers associated with a vertex do not pass this cut. All
1238 tracks associated with a vertex are then used to calculate a track length weighted
1239 average of the θ -angle. Of all the vertices that do pass, only the vertex with the most
1240 forward going θ -angle average of all associated tracks is considered the neutrino vertex
1241 candidate. The most forward going θ -angle average is chosen by picking the largest
1242 track range weighted average of $|\cos(\theta)|$, seeing as $\cos(\theta) = 1$ is the beam direction.
1243 Next, it is required that the reconstructed neutrino vertex candidate be within the
1244 fiducial volume as well as within the drift time starting at t_0 . The fiducial volume
1245 boundaries chosen are 10 cm from the edges of the TPC in x and z which is the drift
1246 direction and beam direction respectively, and 20 cm from the edges of the TPC in y
1247 which is the vertical direction. For all further cuts, only the longest track associated
1248 with the neutrino vertex candidate and this track is assumed to be the muon candidate
1249 of the neutrino event.

1250 The next cut requires the position of the flash in the z-direction and the track z-
1251 projection to be compared. This basic flash matching algorithm is rudimentary and a
1252 placeholder for a more sophisticated algorithm. The z-position of the flash needs to be
1253 within 80 cm to the z-positions of track start or endpoints. If the flash is between the
1254 track start and endpoint, the distance of the flash to the track is considered to be 0 cm.

1255 Lastly, the track needs to be fully contained within the fiducial volume and have a
 1256 track range greater than 75 cm. The range is the 3D distance between the track's start
 1257 and endpoint. The length cut was optimized to remove NC background that contain
 1258 a pion due to the pion interaction rate to be ~ 70 cm. A track that makes all the cuts
 1259 is considered to be the muon of a ν_μ CC event. The list of cuts for this selection is
 1260 described below:

- 1261 1. At least one flash > 50 PE within the beam gate.
- 1262 2. At least one track within 5 cm around a vertex.
- 1263 3. Vertex with flattest tracks is chosen to be vertex candidate.
- 1264 4. Vertex candidate in fiducial volume.
- 1265 5. Longest track associated with vertex candidate is chosen to be track candidate.
- 1266 6. Longest track is within 80 cm (z-axis only) of the flash.
- 1267 7. Longest track is fully contained.
- 1268 8. Longest track is greater than 75 cm.

1269 The event selection scheme can also be seen in figure 5.5. Table 5.1 lists the passing
 1270 rates for MC events for the selection scheme described above. Table 5.2 lists the passing
 1271 rates for on-beam and off-beam data for the selection scheme. The normalization
 1272 factors applied between on-beam and off-beam data are described in section 5.2.

1273 5.5.1 Expected Backgrounds

1274 Most of the selected background events will be of cosmic origin. There are two types
 1275 of cosmic background, one triggered by a cosmic-ray event occurring in the beam
 1276 gate time window, the other triggered by a beam induced interaction in the cryostat
 1277 followed by a misidentification of a cosmic event as a neutrino event. The first
 1278 cosmic background can be subtracted from the selected events using the off-beam
 1279 BNBEXT sample normalized to the on-beam. The second cosmic background events
 1280 are modeled by MC by using BNB+Cosmic MC sample.

1281 Other backgrounds originate from neutrino beam contaminants. A major contribu-
 1282 tion in this sector is by neutral current neutrino events for example a charged pion track
 1283 misidentified as a muon. Another contribution are ν_e -like and anti-muon-neutrino

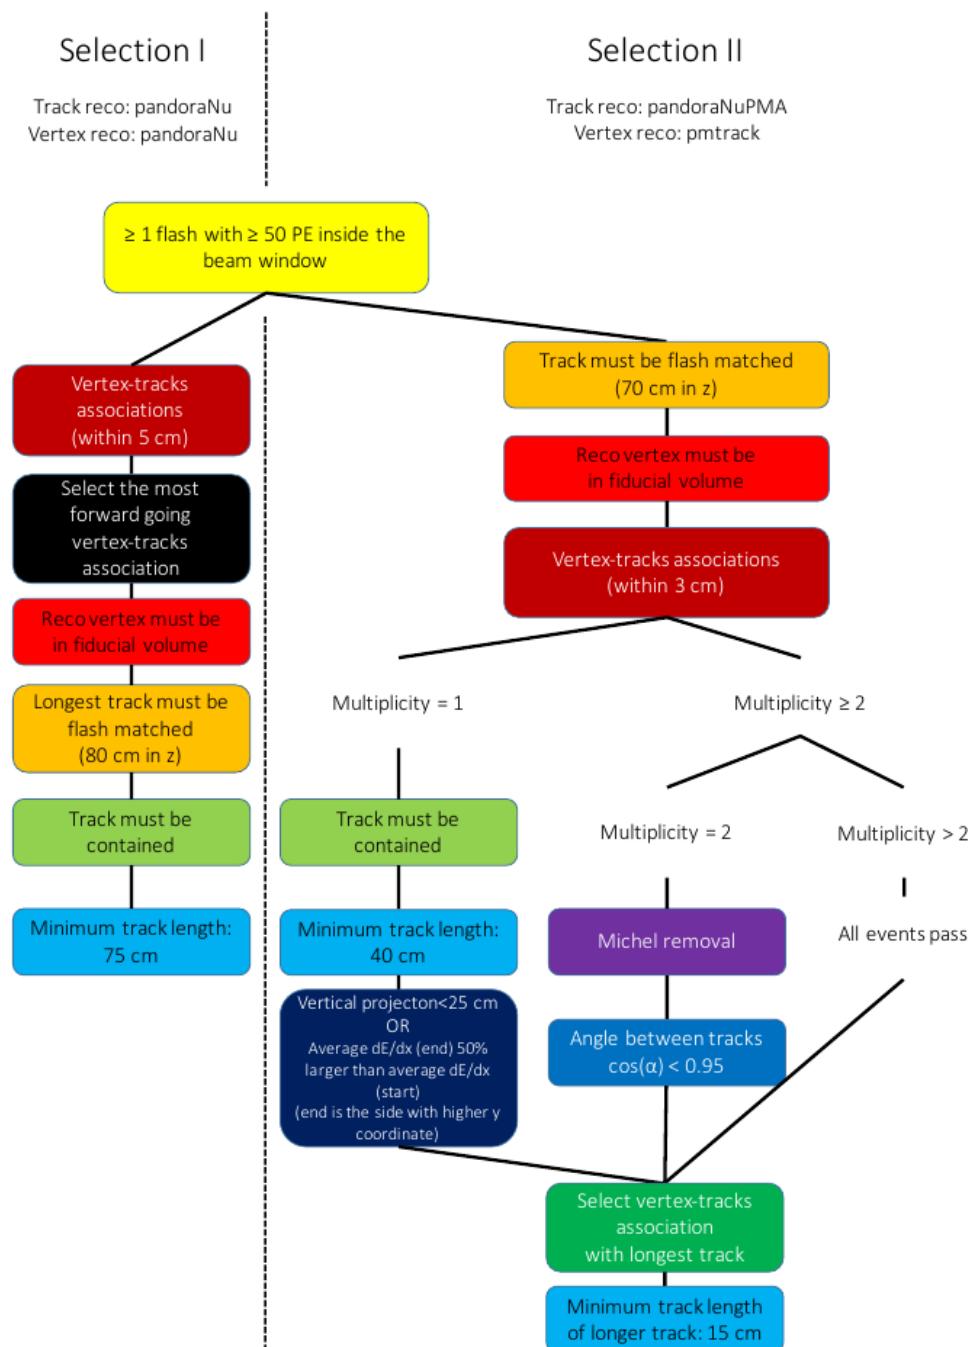

Figure 5.5: Event selection diagram for selection I and selection II. This analysis focused on optimizing selection I. Boxes with the same color across the two selections symbolize similar cuts.

	BNB+Cosmic Selection	BNB+ Cosmic MC-Truth	Cosmic Only	Signal:Cosmic Only
Generated Events	191362	45273	4804	1:22
≥ 1 flash with ≥ 50 PE	136219 (71%/71%)	44002 (97%/97%)	2970 (62%/62%)	1:14
≥ 1 track within 5 cm of vertex	135830 (99%/71%)	43974 (99%/97%)	2975 (99%/62%)	1:14
vertex candidate in FV	79112 (58%/41%)	34891 (79%/77%)	1482 (50%/31%)	1:8.9
flash matching of longest track	40267 (51%/21%)	25891 (74%/57%)	340 (23%/7.1%)	1:2.8
track containment	19391 (48%/10%)	11693 (45%/26%)	129 (38%/2.7%)	1:2.3
track ≥ 75 cm	6920 (36%/3.6%)	5780 (49%/13%)	17 (13%/0.4%)	1:0.6

Table 5.1: Passing rates of Selection I. Numbers are absolute event counts and cosmic background is not scaled. The BNB+Cosmic sample contains all events, not just ν_μ CC inclusive. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt total generated events (second percentage). The BNB+Cosmic MC-Truth column shows how many true ν_μ CC inclusive events are left in the sample. This number includes mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The cosmic only sample is used just to illustrate the cut efficiency. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in section 5.2.

	on-beam	off-beam
Generated Events	546910	477819
≥ 1 flash with ≥ 50 PE	135923 (25%/25%)	96748 (20%/20%)
≥ 1 track within 5 cm of vertex	134744 (99%/25%)	95778 (99%/20%)
vertex candidate in FV	74827 (55%/14%)	51468 (54%/11%)
flash matching of longest track	22059 (29%/4.0%)	12234 (24%/2.6%)
track containment	10722 (49%/1.9%)	5283 (43%/1.1%)
track ≥ 75 cm	3213 (30%/0.6%)	1328 (25%/0.3%)

Table 5.2: Passing rates for Selection I selection applied to on-beam and off-beam data. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). Off-beam data has been scaled with a factor 1.23 to normalize to the on-beam data stream.

1284 events. These beam related backgrounds are an order of magnitude smaller than the
1285 cosmic misidentification backgrounds. These backgrounds can not be subtracted and
1286 are estimated using MC truth.

1287 The efficiency and purity of Selection I are calculated below:

- 1288 • Efficiency: Number of selected true ν_μ CC events divided by the number of
1289 expected true ν_μ CC events with interaction in the FV.
 - 1290 – $(12.3 \pm 3.4) \%$
- 1291 • Purity: Number of selected true ν_μ CC events divided by the sum of itself and
1292 the number of all backgrounds.
 - 1293 – $(53.8 \pm 4.4) \%$

1294 5.5.2 Truth Distributions

1295 The truth distributions of MC truth variables before and after the selection are detailed
1296 in this section. The overall efficiencies are calculated for all ν_μ CC signal events
1297 with a true interaction within the fiducial volume and a fully contained muon track
1298 originating from said vertex. Figures 5.6 through 5.8 detail the truth distributions for
1299 muon momentum, $\cos(\theta)$ and ϕ and figures 5.9 through ?? detail the total efficiency of
1300 the selection for charged current quasi elastic (CCQE) events, charged current resonant
1301 (CCRES) events, and charged current deep inelastic (CCDIS) events.

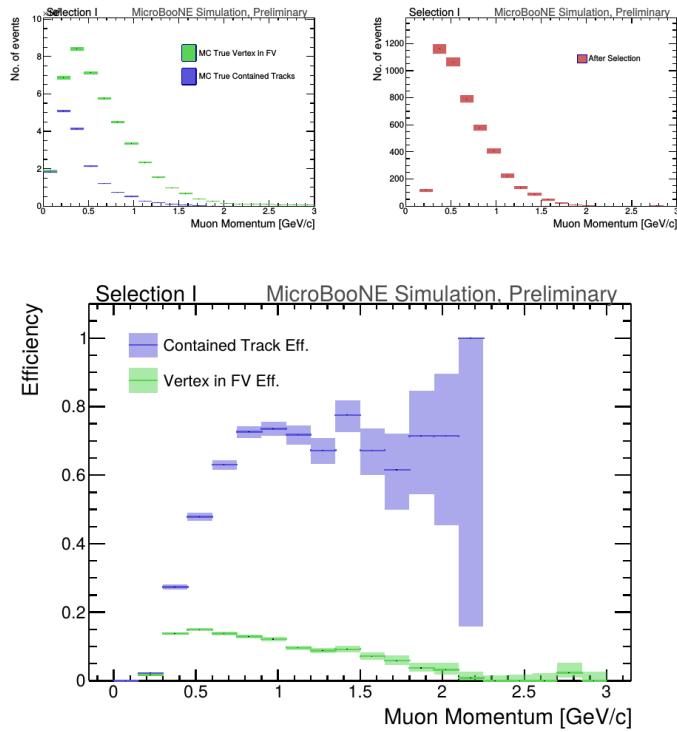

Figure 5.6: MC momentum distributions of the muon originating from a ν_μ CC interaction. Upper left is the momentum distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the momentum distribution after the selection (red). The lower plot is the selection efficiencies.

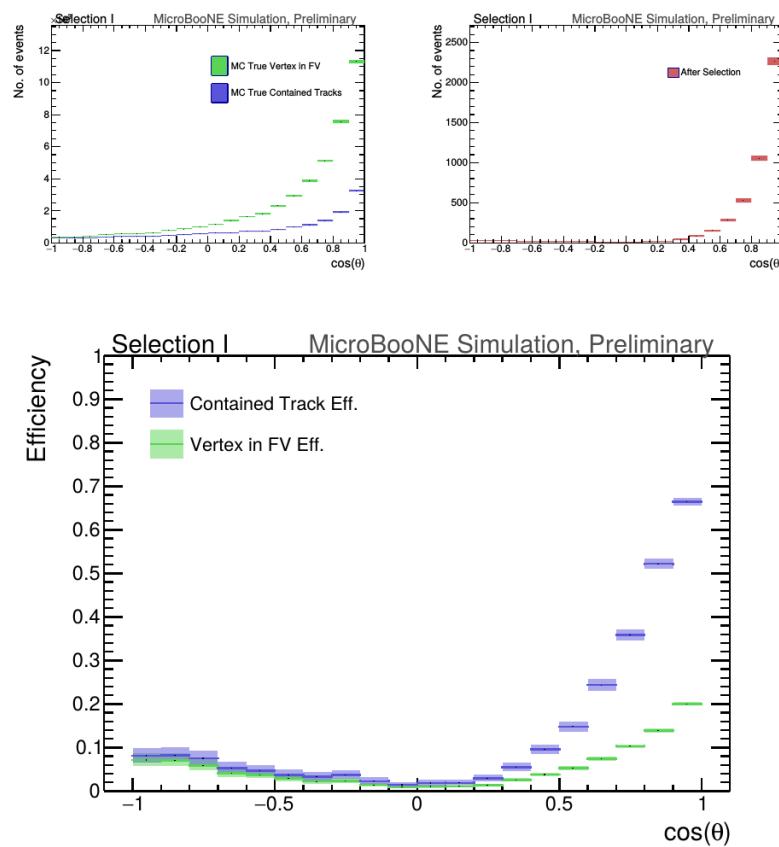

Figure 5.7: MC $\cos(\theta)$ distributions of the muon originating from a ν_μ CC interaction. Upper left is the $\cos(\theta)$ distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the $\cos(\theta)$ distribution after the selection (red). The lower plot is the selection efficiencies.

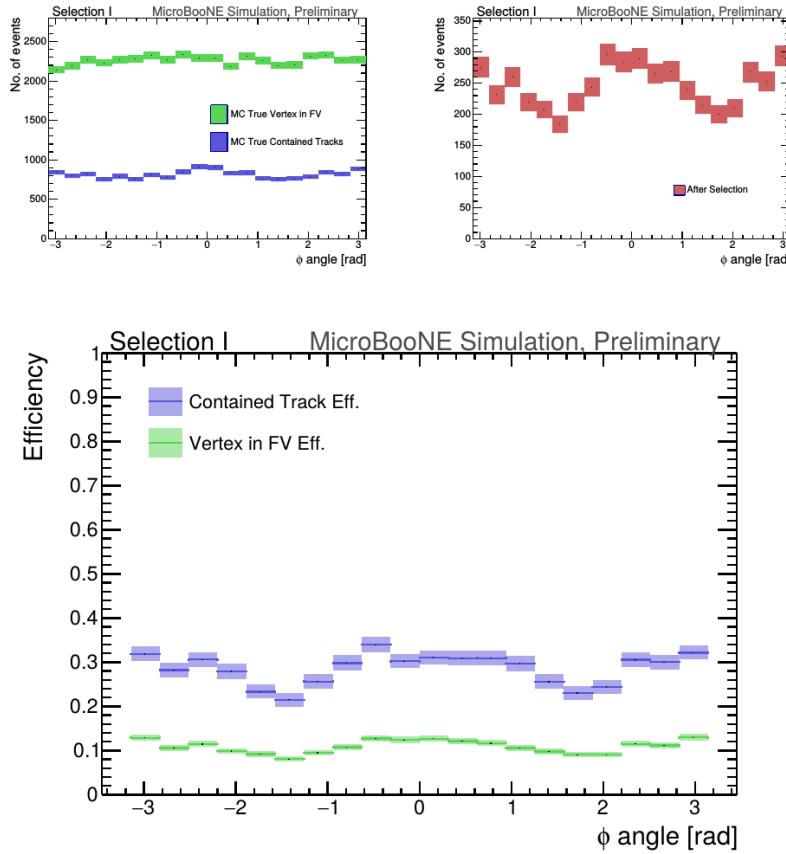

Figure 5.8: MC ϕ distributions of the muon originating from a ν_μ CC interaction. Upper left is the ϕ distributions of events with a vertex within the FV (green) and the events with a fully contained track (blue) before the selection. The upper right side is the ϕ distribution after the selection (red). The lower plot is the selection efficiencies.

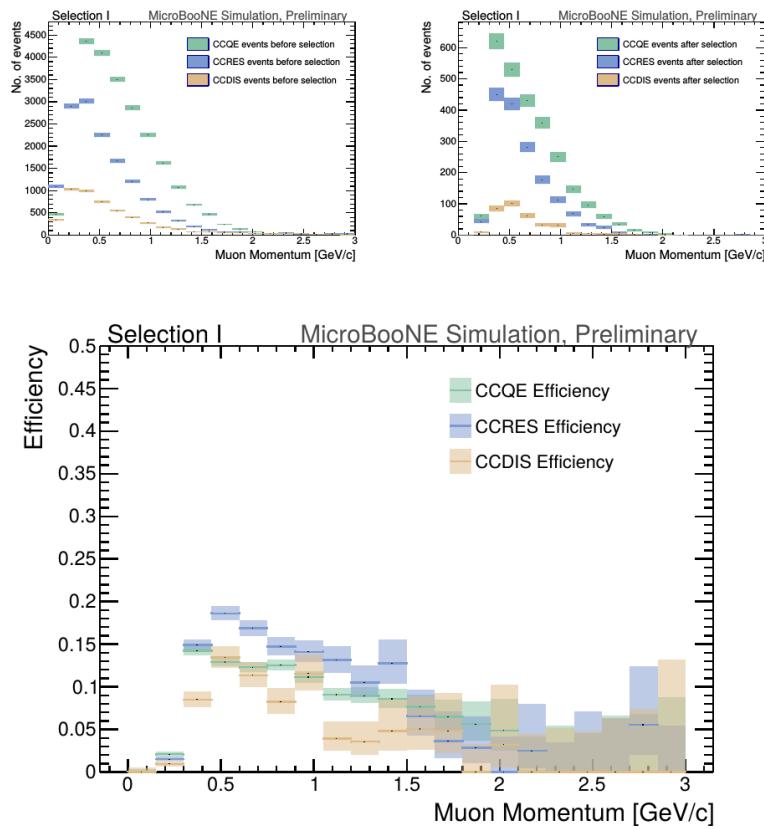

Figure 5.9: MC momentum distributions of the muon originating from a ν_μ CC interaction. Upper left is the momentum distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the momentum distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.

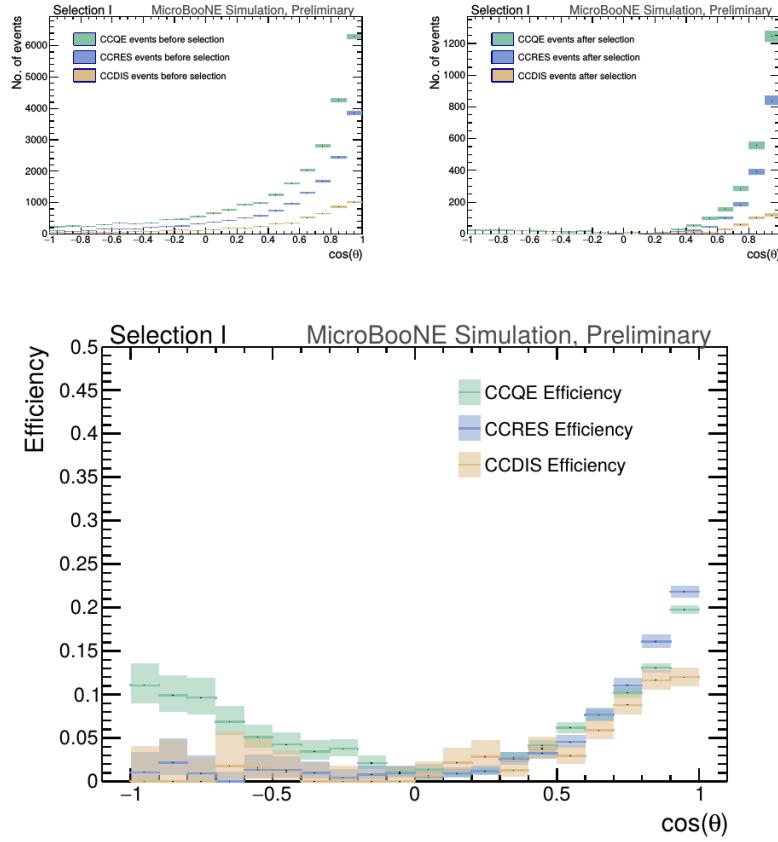

Figure 5.10: MC $\cos(\theta)$ distributions of the muon originating from a ν_μ CC interaction. Upper left is the $\cos(\theta)$ distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the $\cos(\theta)$ distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.

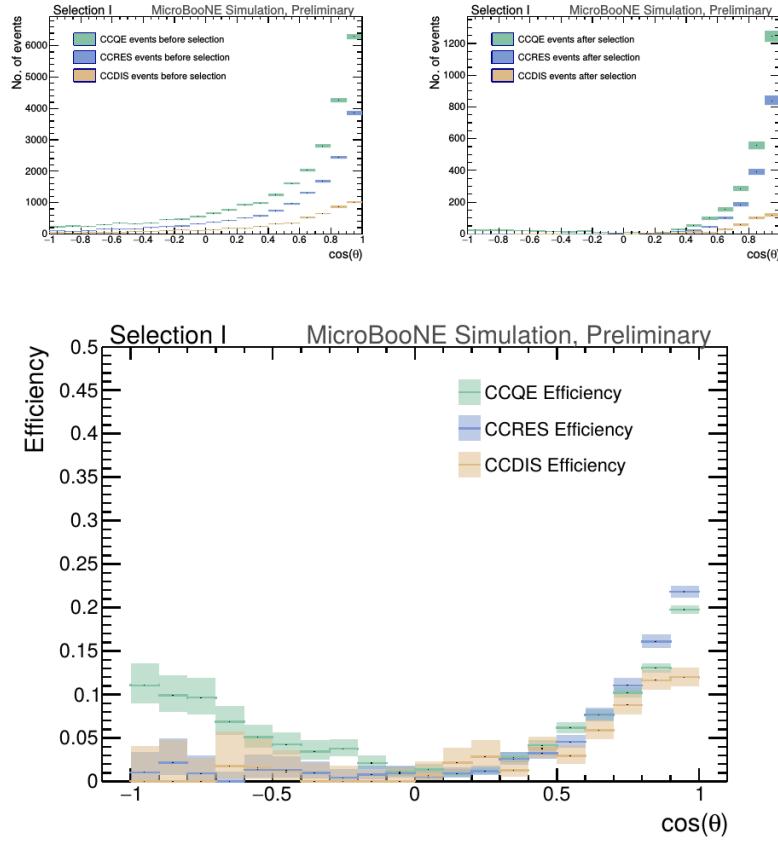

Figure 5.11: MC ϕ distributions of the muon originating from a ν_μ CC interaction. Upper left is the ϕ distributions of events with a vertex within the FV split up into CCQE (red), CCRES (yellow), and CCDIS (green) before selection. The upper right side is the ϕ distribution after the selection with the same color schemes. The lower plot is the selection efficiencies for all three interaction types. The definition of QE, RES, and DIS is based on GENIE.

1302 **Chapter 6**

1303 **Background on Convolutional Neural
1304 Networks**

1305 Convolutional neural networks (CNNs) have been one of the most influential inno-
1306 vations in the field of computer vision. Neural networks became popular in 2012
1307 when Alex Krizhevsky used them to win that year's ImageNet competition [?] by
1308 dropping the error from 26% to 15%. Since then, many companies are using deep
1309 learning including Facebook's tagging algorithms, Google for their photo search and
1310 Amazon for product recommendations. For the purpose of this thesis CNNs were
1311 used for image classification, specifically, images of varying particles created using
1312 LArTPC data.

1313 **6.1 Image Classification**

1314 Image classification is the process of inputting an image into the CNN and receiving a
1315 probability of classes that best describes what is happening in the image. As humans,
1316 image classification is something that is learned at a very young age and is easy to
1317 do without much effort. This is also apparent when hand-scanning LArTPC images.
1318 After learning what a neutrino event looks like in MicroBooNE, it is relatively easy
1319 to recognize simple neutrino events from cosmic ray background as well as highly
1320 ionizing particles like protons from minimum ionizing particles like muons. The very
1321 detailed images LArTPC detectors output are prime candidates for input images into
1322 a CNN. CNNs mimic a human's ability to classify objects by creating an architecture
1323 that can learn differences between all the images it's given as well as figure out the

unique features that make up each object. CNNs are modeled after the visual cortex. Hubel and Wiesel [?] found that there are small regions of neuronal cells in the brain that respond to specific regions of the visual field. They saw that some neurons fired when exposed to vertical edges while others fired when shown horizontal or diagonal edges. They also saw that these neurons were organized in columns. The idea of specific neurons inside of the brain firing to specific characteristics is the basis behind CNNs.

6.2 CNN Structure

When used for image recognition, convolutional neural networks consist of multiple layers that extract different information on small portions of the input image. How many layers is tunable to increase the accuracy. The output of these collections are then tiled so that they overlap to gain a better representation of the original image and allow for translation. The first of these layers is always a convolution layer. To the CNN, an image is an array of pixel values. For a RGB color image with width and height equal to 32x32 the corresponding array is 32x32x3. Filters, also known as neurons, of any size set by the user is then convolved with the receptive field of the image. If the filter is 5x5, the receptive field will be a patch of 5x5 on the input image. The filter is also an array of numbers called weights. The convolution of the filter and image are matrix multiplications of the weights and the pixel values. By stepping the receptive field by 1 unit, for an input image of 32x32x3 and a filter of 5x5x3 you'd get an output array of 28x28x1. This output array is called an activation map or feature map. The use of more filters preserves the spatial dimensions better. The filters can be described as feature identifiers. Examples of features in an image consist of edges, curves, and changes in colors. The first filters in a CNN will primarily be straight line and curve feature identifiers. An example of a curve filter is shown in figure 6.2. When a curve in the same concavity is found in the input image, the corresponding pixel in the output feature map will be activated. Going back to our example of a 32x32 input image and a 5x5 filter, if there were to be a curve in the top left corner of the input image, our output feature map would have a high pixel value in the top left. Therefore, feature maps tell us where a specific feature is located in the original image. Figure ?? shows a visualization of filters found in the first layers of many CNN architectures. These filters in the first layer convolve around the image and activate when the specific feature it is looking for is in the receptive field.

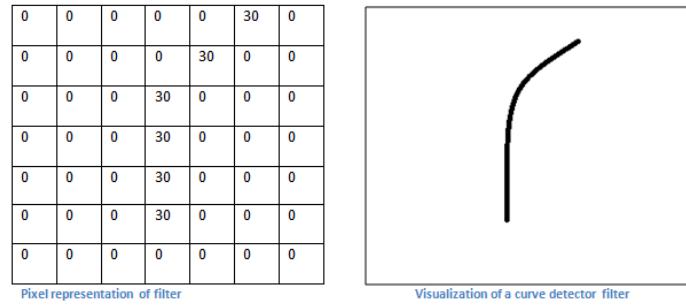

Figure 6.1: Pixel representation and visualization of a curve detector filter. As you can see, in the pixel representation, the weights of this filter are greater along a curve we are trying to find in the input image

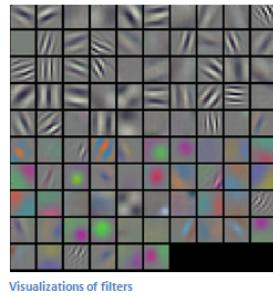

Figure 6.2: Visualization of filters found in first layer of a CNN.

1357 In figure 6.3 you can see how an edge detection filter is used to save only necessary
 1358 information for recognizing different types of clothes. You can also see by having
 1359 multiple filters you can get more detail or less detail from an image which can then
 1360 simplify or complicate the object recognition task. Being able to distinguish between a
 1361 shirt or a leg garment is as much information you want, having a filter that extracts
 1362 outline edge or shape information would be all that you need. But if instead you
 1363 wanted to distinguish between a formal cocktail dress or a summer dress, more
 1364 information would need to be saved equating to many more filters for one image.
 1365 Rather than trying to come up with how many filters and what features are important
 1366 for detection, CNNs do this automatically. CNNs take input parameters, called
 1367 hyperparameters, for example number of layers, number of filters per layers, number
 1368 of weights per filter, and uses these to create the output feature maps. The layers build
 1369 upon each-other, for example if we were creating a CNN for facial recognition the
 1370 convolutional layers will start learning feature combinations off of the previous layers.
 1371 The low level features like edges, gradients, and corners of the first layers become high
 1372 level features like eyes, noses, and hairs. This process is visualized in figure 6.4

Figure 6.3: Applying a feature mask over a set of fashion items to extract necessary information for auto-encoding. Unnecessary information for example color or brand emblems are not saved. This feature map is an edge detection mask that leaves only shape information which helps to distinguish between different types of clothes.

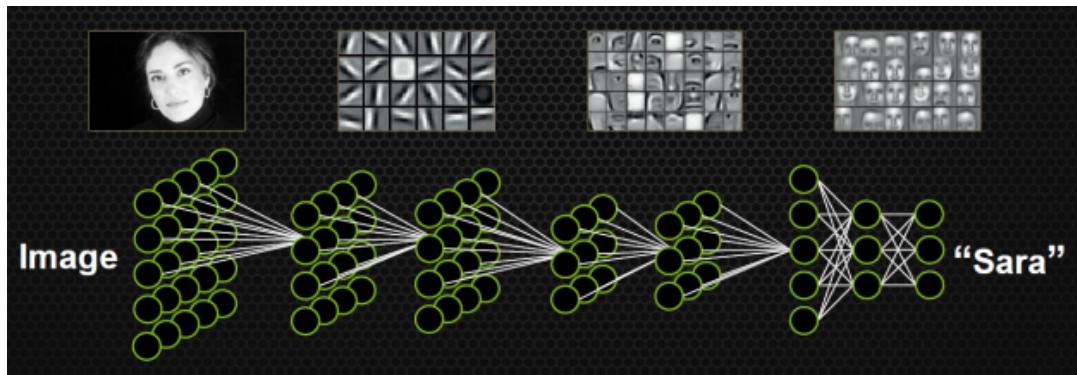

Figure 6.4: Pictorial Representation of Convolutional Neural Networks as well as a visual representation on CNN's complexity of layer feature extraction

1373 There are other layers in a CNN architecture that will not be covered in the scope
 1374 of this thesis but in a general sense, these layers are interspersed between convolution
 1375 layers to preserve dimensionality and control overfitting of the network. The last layer
 1376 is called a fully connected layer and it's job is to output an N dimensional vector where
 1377 N is the number of classes the network has been trained on. Each number in this vector
 1378 represents the probability that the input image is a certain class. Fully connected layers
 1379 use the feature maps of the high level features to compute the products between the
 1380 weights of the previous layer to get the probabilities of each class. These weights are
 1381 then adjusted through the training process using backpropagation.

1382 6.2.1 Backpropagation

1383 A CNN at it's onset has weights that are randomized. The filters themselves don't
 1384 know how to pull out identifying information per class. For a neural network to learn,
 1385 it must be trained on a training set that is labeled. Backpropagation has four seperate
 1386 steps: foward pass, loss function, backward pass and updating weights. In the forward
 1387 pass, a training image is passed through the whole network. All of our weights at this
 1388 time are randomly initialized so the output for the first image will have no preference
 1389 to a specific class. A common loss function is mean squared error (MSE):

$$E_{total} = \sum \frac{1}{2} (actualclass - predictedclass)^2 \quad (6.1)$$

1390 If we assume that the MSE is the loss of our CNN, the goal would be that our
 1391 predicted label (output of CNN) is the same as our training label. To do this, we need
 1392 to minimize the loss function. To do this, it is necessary to find out which weights most
 1393 directly affect the loss of the network i.e $\frac{dL}{dW}$ where L is our loss function and W are
 1394 the weights of a specific layer. The next step is the backward pass which determines
 1395 which weights contribute the most to the loss and finds ways to adjust these weights
 1396 so that the loss decreases. After the derivative is computed, the last step updates the
 1397 weights in the opposite direction of the gradient.

$$w = w_i - \eta \frac{dL}{dW} \quad (6.2)$$

$$w = \text{Weight} \quad (6.3)$$

$$w_i = \text{Initial Weight} \quad (6.4)$$

$$\eta = \text{Learning Rate} \quad (6.5)$$

1398 The learning rate is a parameter given to the CNN and it describes the steps the
 1399 network takes to update the weights. Higher learning rate equals large steps and a
 1400 lower training time, but a learning rate that is too large can mean the CNN never
 1401 converges.

1402 Going through backpropagation consists of one training iteration. Once the net-
 1403 work completes a specific number of iterations, another parameter given, and runs
 1404 over all training images that are split up into batches, the process is considered com-
 1405 plete. User input parameters, called hyperparameters, help the network converge to

¹⁴⁰⁶ optimal weights for each layer. Batch size, learning rate, and training iteration are just
¹⁴⁰⁷ some of the user input hyperparameters that help. Lastly, to check if the network has
¹⁴⁰⁸ learned, a different set of labeled images are fed to the CNN iteratively through the
¹⁴⁰⁹ training process to see how well it's learning. This process is especially important to
¹⁴¹⁰ make sure the network architecture isn't being affected by overfitting (memorizing
¹⁴¹¹ training input rather than learning).

¹⁴¹² 6.3 Choosing Hyperparameters

¹⁴¹³ Convolutional neural networks are a relatively new tools in computer vision. Choosing
¹⁴¹⁴ hyperparameters for your specific dataset is a non-trivial task. Hyperparameters can
¹⁴¹⁵ range from the amount of layers and filters per layer in an CNN architecture to the
¹⁴¹⁶ stride the receptive field of a filter takes, not to mention training hyperparameters
¹⁴¹⁷ such as learning rate and batch size described above. They're ways to optimize these
¹⁴¹⁸ hyperparameters via hyperparameter optimization using Bayesian Optimization [?]
¹⁴¹⁹ but as you can imagine, optimizing an CNN architecture from scratch can be very
¹⁴²⁰ computationally intensive. For the purpose of this thesis, two well known CNN
¹⁴²¹ architectures were used, AlexNet [?], which won the ImageNet Large-Scale Visual
¹⁴²² Recognition Challenge (ILSVRC) in 2012 and therefore bringing awareness of CNNs,
¹⁴²³ and GoogleNet [?], which won the ILSVRC in 2014, giving rise to deep networks. Both
¹⁴²⁴ AlexNet and GoogleNet architectures were used to train on LArTPC images and their
¹⁴²⁵ low level filter weights. Higher level filter weights were randomly initialized before
¹⁴²⁶ training so the network can learn high level features of LArTPC image classes. The
¹⁴²⁷ AlexNet architecture is shown in figure 6.5 and the GoogleNet architecture is shown
¹⁴²⁸ in figure 6.6

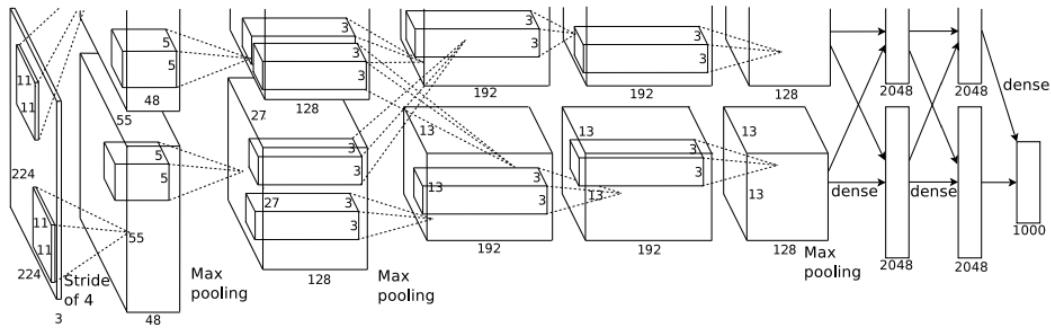

Figure 6.5: Pictoral representation of the AlexNet model. The AlexNet model consists of 5 convolution layers and 3 fully connected layers.

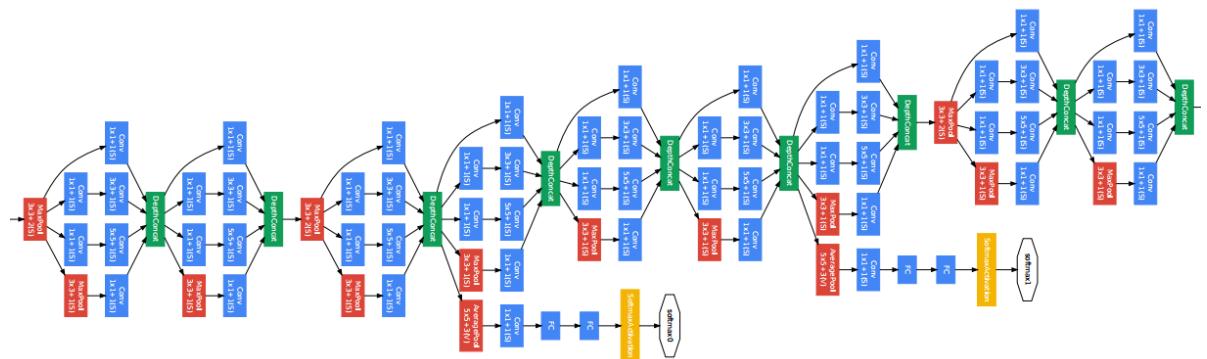

Figure 6.6: Pictoral representation of the GoogleNet model. The GoogleNet model consists of 22 layers. The model implements 9 Inception modules which performs covolution and pooling in parallel and strays away from the basis that CNN layers need to be stacked up sequentially. The GoogleNet model also doesn't use fully connected layers, instead it uses average pooling which greatly reduces the amount of parameters. GoogleNet has 12x fewer parameters than AlexNet.

¹⁴²⁹ **Chapter 7**

¹⁴³⁰ **Training Convolutional Neural
1431 Networks on particles WORKING
1432 TITLE**

¹⁴³³ Three Convolutional Neural Networks (CNNs) were trained throughout this analysis.
¹⁴³⁴ There are differences to each CNN and will be described fully in the next sections but
¹⁴³⁵ the main difference are the amount of particle images used for training and validation.
¹⁴³⁶ CNN1075 used 1,075 muons and 1,075 pions for training and the same amount of each
¹⁴³⁷ particle for validation. CNN10000 used 10,000 muons and 10,000 pions split in half
¹⁴³⁸ for testing and training. Lastly CNN100000 had muons, pions, protons, electrons,
¹⁴³⁹ and gammas in its training and validation set. Each particle had 20,000 images and
¹⁴⁴⁰ training and validation was split 90% training, 10% validation. This chapter will also
¹⁴⁴¹ describe the different hardware frameworks used for training beginning on a CPU
¹⁴⁴² and ending on a GPU cluster.

¹⁴⁴³ **7.1 Hardware Frameworks used for Training**

¹⁴⁴⁴ **7.1.1 Syracuse CPU Machine setup**

¹⁴⁴⁵ **7.1.2 Syracuse University GPU Cluster Setup**

¹⁴⁴⁶ **7.2 Convolutional Neural Network Training**

¹⁴⁴⁷ **7.2.1 Image Making Scheme**

¹⁴⁴⁸ **Images used for Traing/Validation of Convolutional Neural Networks**

¹⁴⁴⁹ The μ/π image dataset used to train and validate CNN1075 was created using single
¹⁴⁵⁰ generated isotropic muons and pions from 0-2 GeV energy range. 2,150 muons and
¹⁴⁵¹ 2,150 pions were used for training and testing split 50 %. The images were created
¹⁴⁵² based on wire number and time tick in the collection plane. Uboonecode reconstruction
¹⁴⁵³ version v05_08_00 was used. The raw ADC value after noise filtering was the wire
¹⁴⁵⁴ signal. Each collection plane grayscale image was 3456x1600x1 where 6 time ticks
¹⁴⁵⁵ were pooled into 1 bin. After the image was created, the region of interest (ROI) in
¹⁴⁵⁶ the image was found by using Open CV, a image processing open source software
¹⁴⁵⁷ package, to scan the image starting from the edges and stopping once a bright spot is
¹⁴⁵⁸ encountered. Thi

¹⁴⁵⁹ The μ/π image dataset used to train and validate the CNN10000 was also created
¹⁴⁶⁰ using single generated isotropic muons and pions from 0-2 GeV energy range. 10,000
¹⁴⁶¹ muons and 10,000 pions were used for training and testing split 50%. Uboonecode
¹⁴⁶² v06_23_00 was used instead of v05_08_00. Each collection plane grayscale image was
¹⁴⁶³ 3456x1280x1 where 5 time ticks were pooled into 1 bin which is different than the
¹⁴⁶⁴ previous dataset and was implemented due to the fact that the time ticks of an event
¹⁴⁶⁵ went from 9400 to 6400 with the change of uboonecode version. The grayscale color
¹⁴⁶⁶ standard is 8bit therefore the ADC value of wire and time tick was also downsampled
¹⁴⁶⁷ due to the 12bit ADC value MicroBooNE has. To do this, the highest ADC pixel in
¹⁴⁶⁸ the image was found and then this was divided by the rest placing all pixel values
¹⁴⁶⁹ between 0-1. From there, all pixel values are then multiplied by 255. All images
¹⁴⁷⁰ were made using a LArSoft module. Once the images were created, using and image

1471 manipulation framework called OpenCV images were read into a numpy array and
1472 cropped to the region of interest by only keeping rows and columns where all ADC
1473 values are higher than 0 and then resized it to 224x224 using OpenCV's resize function.
1474 This downsampling of ADC values creates a problem of information loss for example,
1475 a proton which is highly ionizing will have the same brightness as a minimum ionizing
1476 muon by virtue of how the images are created. Issues that arose in CNN1075 that
1477 were fixed in CNN10000 include zero-padding images in X and Y that are smaller
1478 than 224X224 to eliminate over-zooming effect and fixing a bug that shifted pixels
1479 separated by a dead-wire region.

1480 Images were also made from events that passed the cc-inclusive selection 1 filter
1481 right before the 75 cm track length cut and were classified using the CNN10000. The
1482 dataset used to create these images is the same one used in [?], prodgenie_bnb_nu_cosmic_uboone_mc
1483 These images were created using information from the track candidate that passed
1484 the filter. Only wire number and time ticks associated to the track candidate were
1485 drawn on the image to mimic a single particle generated image. These images were
1486 then classified using CNN10000. Two approaches were taken in making these images.
1487 The first was using the image normalization above where the maximum pixel in each
1488 image is used as a normalization constant to get all pixels between 0-1 then multiply
1489 all pixels by 255. As described above, this is the incorrect way to normalize; it should
1490 be normalized by dataset not by event, which is the second way the images were
1491 created. The results of CNN10000 performance are shown in section 7.2.

1492 7.2.2 Training CNN1075

1493 The work shown in these next sections are based on the previous work done described
1494 in [?]. That CNN (now referred to as CNN1075) was trained using single generated
1495 isotropic muons and pions from 0-2 GeV energy range. 1,075 muons and pions were
1496 used to train the network and 1,075 μ/π were used as a validation set. The accuracy is
1497 how well CNN1075 is doing by epoch and was 74.5%. The loss is gradient descent
1498 or minimization of the error of the weights and biases used in each neuron of each
1499 layer of CNN1075 and was 58% with a trend sloping downwards on the loss curve
1500 as well as a trend sloping upward in the accuracy curve. Due to the depth of the
1501 neural network framework, it was necessary to train with a larger dataset and for
1502 more epochs, however, the downward slope of the loss curve is an indication that once
1503 trained for longer with a higher training sample, neural networks can be used for μ/π

1504 separation. Updates in the image making and downsampling algorithm were made to
1505 fix issues that arose in CNN1075.

1506 **7.2.3 Training CNN10000**

1507 The hyperparameters used for CNN10000 are shown. The batch size for the training
1508 and testing as well as the test iter were chosen to encompass the whole training/testing
1509 image set when doing accuracy/loss calculations. To do this, multiplying the test
1510 iter by the test batch size give you the amount of images used when calculating
1511 accuracy/loss curves. For reference, the accuracy and loss are defined as well.

- 1512 • train_batch_size: 100
- 1513 • test_batch_size: 100
- 1514 • test_iter: 100
- 1515 • test_interval: 100
- 1516 • base_lr: 0.001
- 1517 • lr_policy: "step"
- 1518 • gamma: 0.1
- 1519 • stepsize: 1000
- 1520 • display: 100
- 1521 • max_iter: 10000
- 1522 • momentum: 0.99
- 1523 • weight_decay: 0.0005
- 1524 • snapshot: 100
- 1525 • Accuracy: How often the CNN predicts the truth over total number of images
- 1526 • Loss: Error between truth and prediction. Minimize loss by gradient descent to
1527 update weights and biases of CNN

1528 The same architecure that was used to train CNN1075 was employed on CNN10000,
1529 Imagenet. Caffe [?] was the software package used for both CNNs. The differences

1530 include batch size and test_iter and momentum to account for the larger dataset. Both
 1531 CNNs were trained on a CPU machine, Syracuse01. Further training will be done
 1532 on a GPU cluster stationed at Syracuse University. Figure 7.1 shows the loss and
 1533 accuracy of CNN10000. There is around a 10% increase in accuracy from CNN1075 to
 1534 CNN10000, 85%, and around a 20% decrease in loss, 36%.

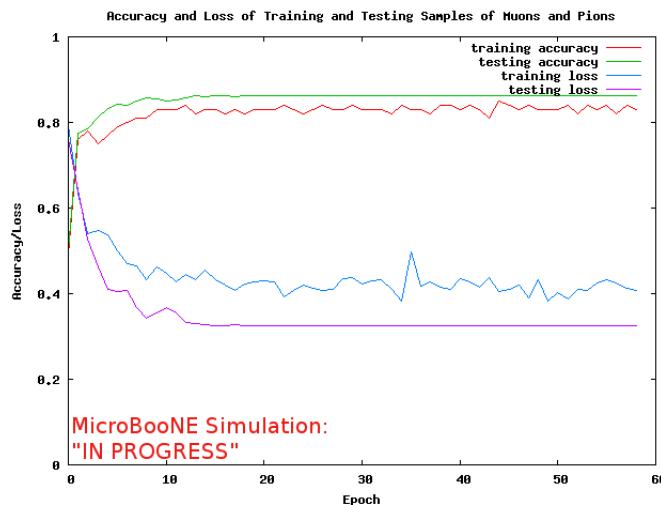

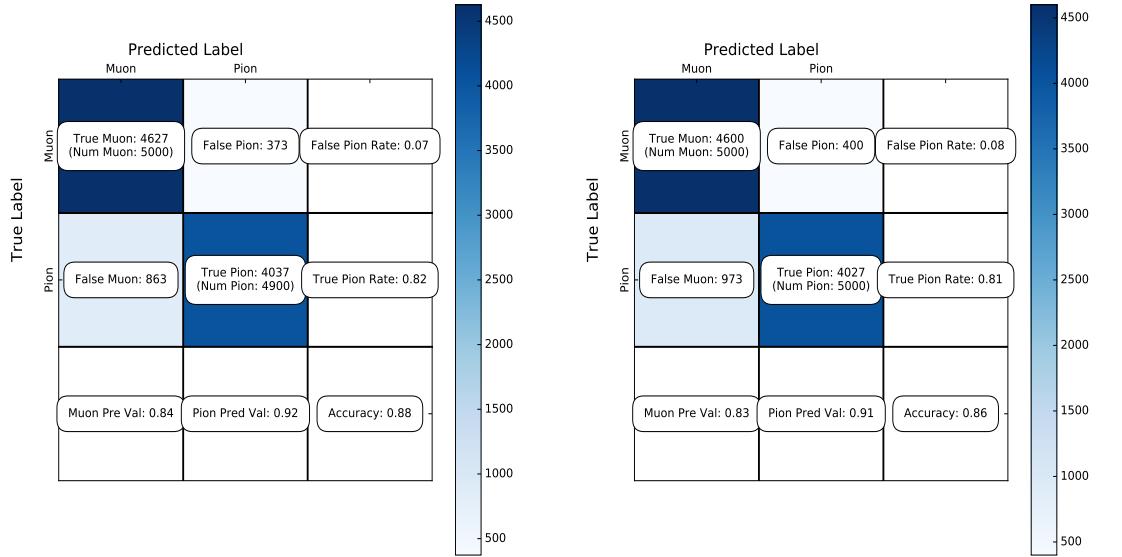

Figure 7.1: Accuracy vs. Loss of ImageNet 2-output μ/π sample consisting of 10000 images each.

1535 Figure 7.2 show a breakdown of μ/π separation for CNN10000. It also shows
 1536 the network is not being overtrained due to the Accuracy of both the training and
 1537 testing datasets being within .01% of eachother. The CNN is doing a very good job of
 1538 classifying true muons as muons, and our loss increase from CNN1075 is due to the
 1539 increase in accurately classifying pions as pions.

1542 **Chapter 8**

1543 **Results of Convolutional Neural
1544 Networks on particles WORKING
1545 TITLE**

1546 **8.1 Classification using CNN10000**

1547 **8.1.1 Classification of MC data using Selection I Original
1548 CC-Inclusive Filter**

1549 The next step that was taken was to use CNN10000 to classify track candidate images
1550 that were identified by the selection I original cc-inclusive filter described in [?].
1551 Passing rates for each cut in cc-inclusive filter are show in figure 8.1. For the incorrect
1552 image making normalization dataset, out of 188,880 events, 7438 passed the cut right
1553 before 75 cm track length cut which is 3.9% of total data. Discrepancies in passing rates
1554 are due to grid submission issues, however, this dataset is used to check if changes
1555 in image making normalization affects μ/π separation probability due to CNN10000
1556 being trained with incorrectly image making normalized data. For the second dataset
1557 with correct image making normalization, out of 188,880 events, 9552 events passed the
1558 cut right before the 75 cm track length cut which is 5.1% passing rate and is comparable
1559 to figure 8.1. In time cosmics were also run over for efficiency and purity calculations.
1560 Out of 14395 in time cosmic events, 175 passed the cut right before the 75 cm track
1561 length cut which is a passing rate of 1.2% compared to 1.3% shown in figure 8.1.

Table 3: **Selection I: Original** The table shows passing rates for the above described event selection. Numbers are absolute event counts and Cosmic background is not scaled appropriately. The BNB+Cosmic sample contains all events, not just ν_μ CC inclusive. The selected events are further broken up in the following subsection. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). In the BNB+Cosmic MC Truth column shows how many true ν_μ CC inclusive events (in FV) are left in the sample. This number includes possible mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The cosmic only sample has low statistics, but please note that it is not used in any plots, it is just for illustrating the cut efficiency. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in chapter 2. Note that this numbers is not a purity, since other backgrounds can't be determined at this step.

	BNB + Cosmic Selection	MC-Truth	Cosmic only	Signal: Cosmic only
Generated events	191362	45273	4804	1:22
≥ 1 flash with ≥ 50 PE	136219 (71%/71%)	44002 (97%/97%)	2979 (62%/62%)	1:14
≥ 1 vertex in FV	131170 (96%/69%)	43794 (99%/97%)	2805 (94%/58%)	1:13
≥ 1 track within 5 cm of vertex	129784 (99%/68%)	43689 (99%/97%)	2756 (98%/58%)	1:13
flash matching of longest track	44775 (34%/23%)	23647 (54%/52%)	647 (23%/13%)	1:5.7
track containment	10114 (23%/5.3%)	6882 (29%/15%)	61 (9.4%/1.3%)	1:1.9
track ≥ 75 cm	7358 (73%/3.8%)	5801 (84%/13%)	31 (51%/0.6%)	1:1.1

Figure 8.1: Snapshot of passing rates of Selection I from CC-Inclusive Filter

Figures 8.2a, 8.2b, 8.2c and 8.2d show the accuracy and μ/π separation of both the correct and incorrect normalized images. The confusion matrices are only composed of μ/π data. Other particles passed the cc-inclusive filter before the 75 cm track length cut and were all mis-id'ed as muons. Since CNN10000 has not seen any particles other than muons and pions, it makes sense that those get mis-id'ed. Figures 8.2b and 8.2d don't have μ/π separation comparable to 7.2c, but 8.2b does skew to higher probabilities compared to 8.2d. This is to be expected and further work on quantifying the performance of CNN10000 should use the incorrect image making normalization. It is also expected that the separation isn't as defined as the testing dataset for CNN10000. CNN10000 was trained and tested using single particle muons and pions and the track candidate dataset come from BNB+Cosmic events, not to mentions all track candidates have passed the cc-inclusive filter that tags "muon-like" tracks therefore the pions in this sample look much closer in muon topology than the network has seen. Also, these images were made from wire and time ticks associated to hits from the track candidate that passed the cc-inclusive filter. This is different from the training images where a bounding box was drawn over the total μ or π interaction. Spurious energy deposition from a $\pi - Ar$ interaction is most likely not included in the BNB+Cosmic images due to the tracking algorithm. To remedy this, the neural network needs to see more "muon-like" pions and muons and pions from a neutrino interaction passing the cc-inclusive filter as well as a larger particle variety including protons, photons

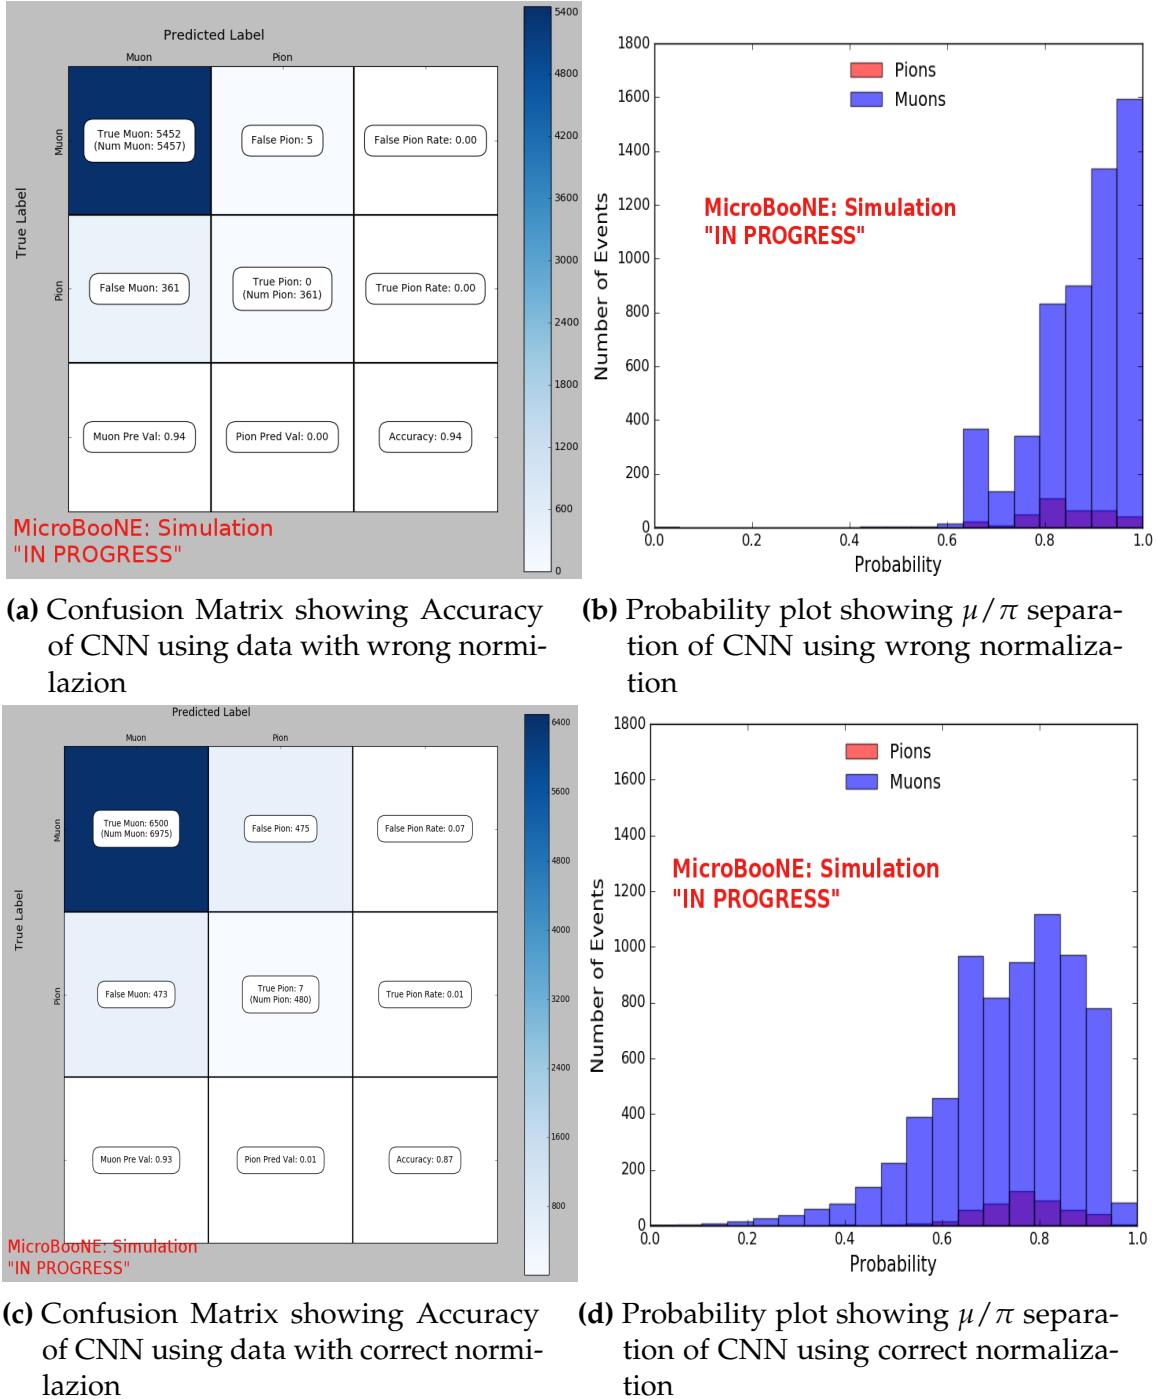

Figure 8.2: Results of CNN10000 classification of track candidate images output from cc-inclusive filter.

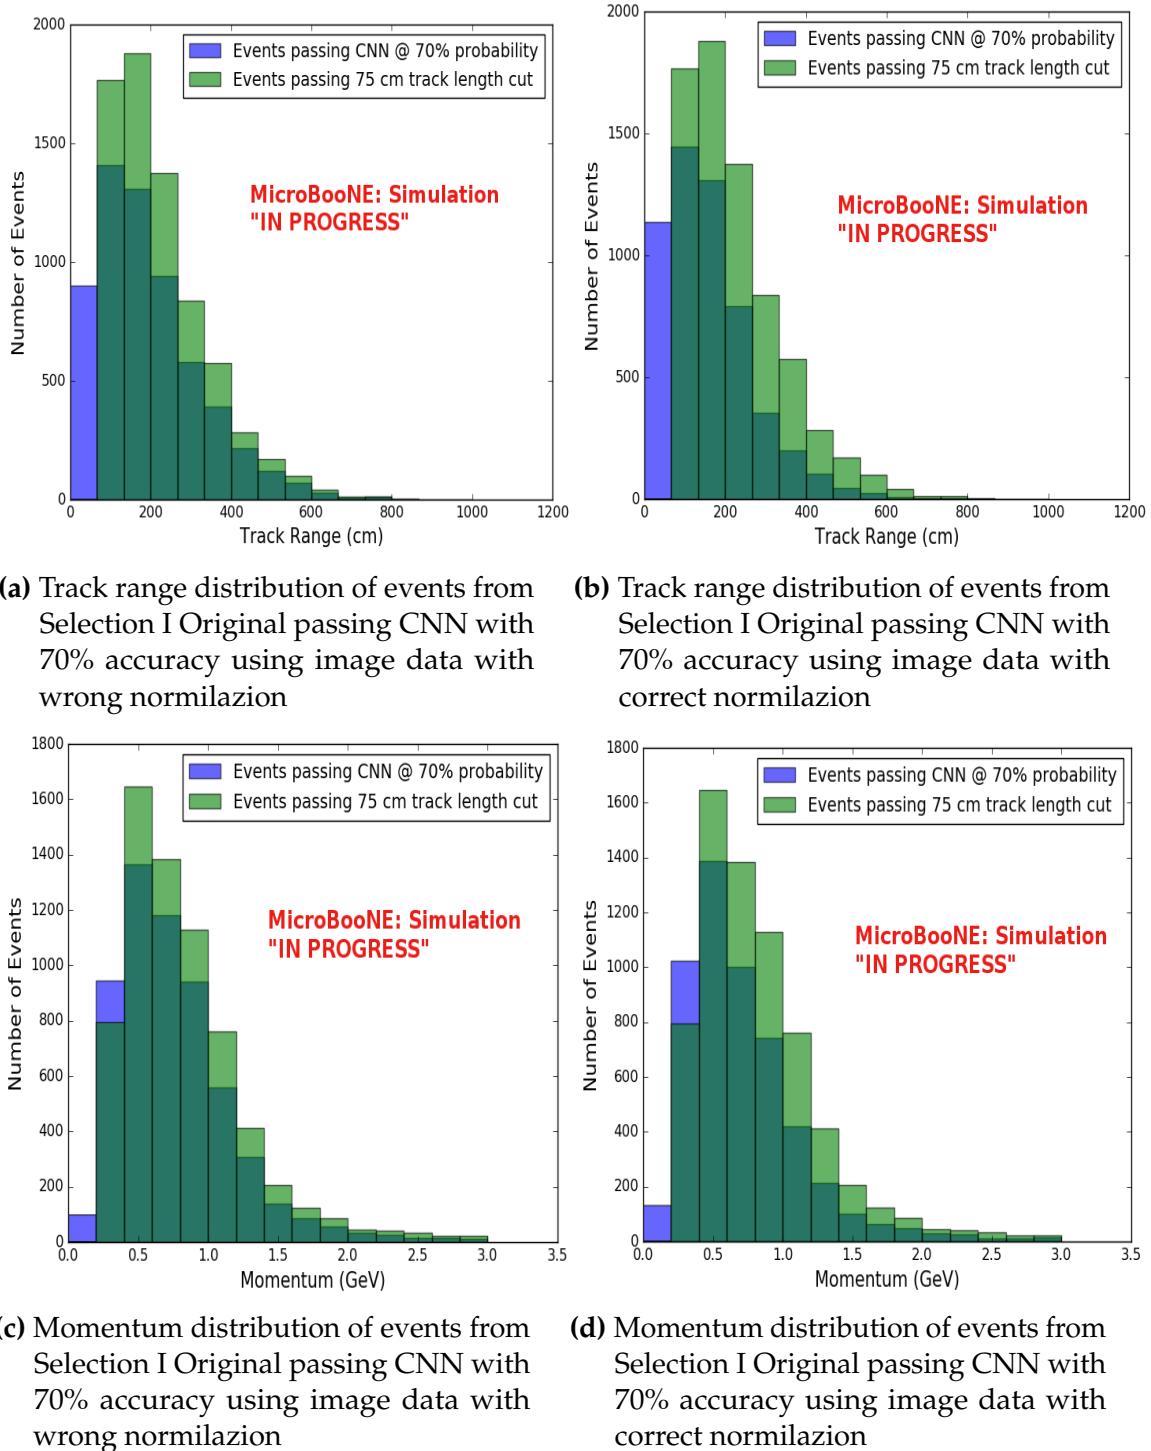

Figure 8.3: CNN10000 distributions of track candidate images output from Selection I Original cc-inclusive filter with different image data normalizations

and electrons. Although μ/π separation is lacking, CNN10000 does an excellent job of classifying muons and using higher CNN probability can increase purity. Figures 8.3a, 8.3b, 8.3c and 8.3d show the track and momentum distributions for these two datasets. In both sets you have an increase in data in the bin below 75 cm and at bins below 0.5 GeV. These distributions were made with events classified with 70% probability of being a muon regardless of true particle type.

8.1.2 Classification of MC data using Selection I Modified CC-Inclusive Filter

Table 5: **Selection I: Modified** The table shows passing rates for the above described event selection. Numbers are absolute event counts and Cosmic background is not scaled appropriately. The BNB+Cosmic sample contains all events, not just ν_μ CC inclusive. The selected events are further broken up in the following subsection. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). In the BNB+Cosmic Mc Truth column shows how many true ν_μ CC inclusive events (in FV) are left in the sample. This number includes possible mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The cosmic only sample has low statistics, but please note that it is not used in any plots, it is just for illustrating the cut efficiency. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in chapter 2. Note that this numbers is not a purity, since other backgrounds can't be determined at this step.

	BNB + Cosmic Selection	MC-Truth	Cosmic only	Signal: Cosmic only
Generated events	191362	45273	4804	1:22
≥ 1 flash with ≥ 50 PE	136219 (71%/71%)	44002 (97%/97%)	2979 (62%/62%)	1:14
≥ 1 track within 5 cm of vertex	135830 (99%/71%)	43974 (99%/97%)	2975 (99%/62%)	1:14
vertex candidate in FV	79112 (58%/41%)	34891 (79%/77%)	1482 (50%/31%)	1:8.9
flash matching of longest track	40267 (51%/21%)	25891 (74%/57%)	340 (23%/7.1%)	1:2.8
track containment	19391 (48%/10%)	11693 (45%/26%)	129 (38%/2.7%)	1:2.3
track ≥ 75 cm	6920 (36%/3.6%)	5780 (49%/13%)	17 (13%/0.4%)	1:0.6

Figure 8.4: Snapshot of passing rates of all cuts from Selection I Modified cc-inclusive filter

CNN10000 was also used to classify track candidate images that were identified by the selection I modified cc-inclusive filter described in [?]. Passing rates for each cut in this filter are shown in figure 8.4. As seen in section 8.1.1, wrong image normalization had a higher muon classification probability so all work done using selection I modified cc-inclusive filter was done using this normalization. Out of 188,880 events, 19,112 passed the cut right before the 75 cm track length cut which is a 10.1% passing rate and comparable to the 10% passing rate shown in figure 8.4. In time cosmics were also run over, out of 14,606 in time cosmics events, 302 passed the cut right before the 75 cm track length cut which is a 2.1% passing rate comparable to the 2.7% passing rate in the cc-inclusive tech-note. Figures 8.5a and 8.5b show the accuracy and μ/π separation. Both plots are only composed of muons and pions and like selection I original data,

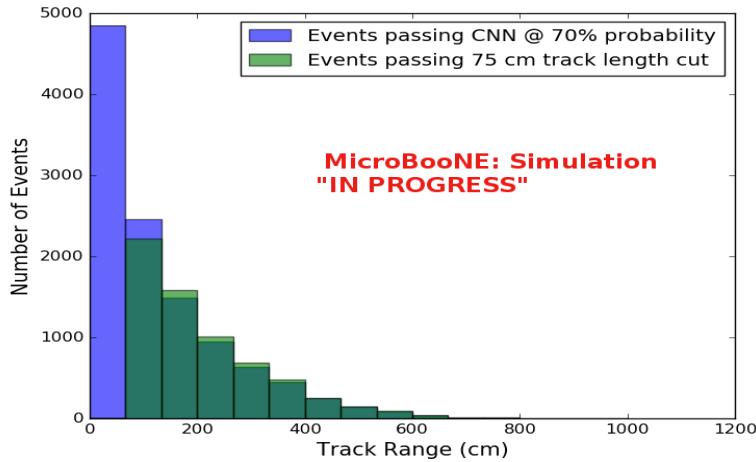

1601 all other particles were id'ed as muons. Also like selection I original data, muons are
 1602 being identified at a very high rate. Figure 8.6a shows the track range distributions
 1603 of all events from selection I modified being classified by the CNN as a muon with a
 1604 probability of 70% regardless of true particle type. We get entries for the CNN curve
 1605 in the lowest bin and none for the 75 cm curve. To see how many true CC events
 1606 were identified by CNN10000 breaking down figure 8.6a by event type was necessary.
 1607 Figures 8.6b and 8.6c show track range distributions separated by signal and various
 1608 backgrounds. Particle type was not taken into consideration in these plots so true CC
 1609 event images can be any track candidate particle passing selection I modified cut right
 1610 before track length cut including pions and protons.

1611 To gain an even deeper understanding on how CNN10000 is performing, plotting
 1612 these distributions with only muons and pions was done due to the fact that CNN10000
 1613 was trained with only those particles for μ/π separation. Figures 8.6d-8.7d show the
 1614 stacked histograms of signal and background of the track range distributions with
 1615 varying CNN probabilities starting from 70% and ending at 90% probability. With
 1616 higher probabilities we get a purer sample in the lower bin but we end up losing
 1617 events as well. Momentum distributions for all signal/background events are shown
 1618 in figure 8.8.

(c) Stacked signal and background momentum distributions from Selection I Modified passing 75 cm track length cut

Figure 8.8: CNN10000 momentum distributions of track candidate images output from Selection I Modified cc-inclusive filter

Another check was to see if any true CC pions were passing through the cut right before the 75 cm track length cut. Figure 8.9 shows the comparison of the stacked track range distribution with only true CC muon signal versus the stacked distribution with true CC muons and pions signal. As you can see, we gain more events when plotting CC events with a particle type of either muons or pions due to the CNN classifying all pions in this dataset as muons. This is an interesting scenario and a sample of topologies of these images are represented in figure 8.10, at least 3 tracks are coming out of the vertex for these types of events. With the 75 cm track length cut, the selection is cutting event topologies like this where the pion is the tagged track candidate. Figure 8.10a has a defined longer muon track, but because of dead wires through the track, the reconstructed range is 1. less than 75 cm and 2. shorter than the reconstructed pion whose length is also less than 75 cm. This is a very interesting event, but because of issues with the tracking algorithm, the 75 cm cut would get rid of this event. The CNN was able to recover this event only because it has classified all pions as muons. Figure 8.10b shows the second case to think about, the pion, while still less than 75 cm has a reconstructed track length longer than the muon. Again, the CNN recovered this event due to pions being classified as muons. Lastly, figure 8.10c shows a pion with a reconstructed track length greater than 75 cm and the muon. These three cases show that a broader question must be asked when training the network other than is it a muon or pion. There are different routes to recover interesting events like these. One route is to ask the network “Is it a CC event or is it an NC event?” and obtain an image dataset consisting of whole CC/NC events that will train the network to answer this question. The other route is to ask the network “Is this a $\mu/\pi/p/$ from a CC event or NC event and obtain an image dataset consisting of primary particles from a CC/NC event. Both these paths will be explored in future work.

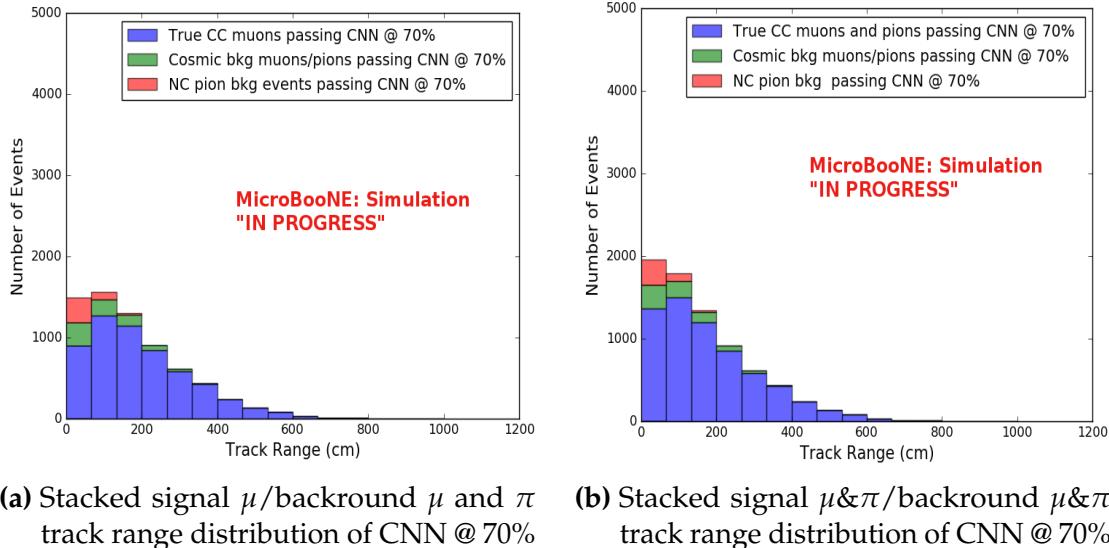

Figure 8.9: Track distribution comparisons of true CC muons plotted vs true CC muons and pions plotted

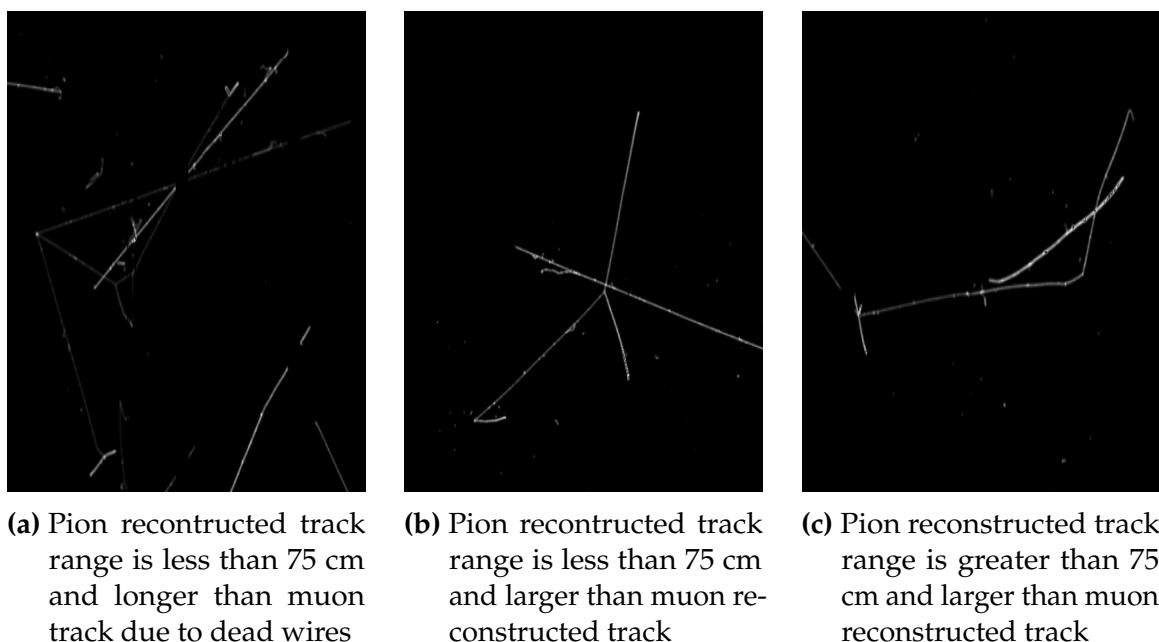

Figure 8.10: Images of true CC events where the pion was the tagged track candidate

		BNB + Cosmics		Cosmic Only	Signal: Cosmic Only
		Selection	MC Truth		
75 cm Cut passing rates	Generated Events	191362	45723	4804	1:22
	Track Containment	19391 (48%/10%)	11693 (45%/26%)	129 (38%/2.7%)	1:2.3
	track \geq 75 cm	6920 (36%/3.6%)	5780 (49%/13%)	17 (13%/0.4%)	1:0.6
CNN passing rates	Generated Events	188880	44689	14606	1:21
	Track Containment	19112 (/10%)	11554 (/26%)	302 (/2.1%)	1:1.73
	CNN cut @ 70% Probability	16502 (86%/8.7%)	10605 (92%/23%)	205 (68%/14%)	1:1.28
	CNN cut @ 83% Probability	7511 (46%/4.0%)	6142 (58%/14%)	32 (16%/0.2%)	1:0.4

Table 8.1: Comparing passing rates of CNN at different probabilities versus 75 cm track length cut: Numbers are absolute event counts and Cosmic background is not scaled appropriately. The BNB+Cosmic sample contains all events. The numbers in brackets give the passing rate wrt the step before (first percentage) and wrt the generated events (second percentage). In the BNB+Cosmic MC Truth column shows how many true ν_μ CC-inclusive events (in FV) are left in the sample. This number includes possible mis-identifications where a cosmic track is picked by the selection instead of the neutrino interaction in the same event. The CNN MC True generated events were scaled wrt the MC True generated events for the 75 cm cut passing rates due to only running over 188,880 generated events versus the 191362 generated events. The last column Signal:Cosmic only gives an estimate of the ν_μ CC events wrt the cosmic only background at each step. For this number, the cosmic background has been scaled as described in [?]. Note that these numbers are not a purity, since other backgrounds can't be determined at this step.

Signal	ν_μ CC events with true vertex in FV	#Events(Fraction)	#Events(Fraction)
		passing CNN @ 70% Probability	
Backgrounds		10605(35%)	#Events(Fraction) passing CNN @ 83% Probability
	Cosmics Only Events	13573(45%)	
	Cosmics in BNB Events	2249(7.4%)	
	NC Events	3412(11%)	
	ν_e and $\bar{\nu}_e$ Events	139(0.5%)	
	$\bar{\nu}_\mu$ Events	97(0.3%)	

Table 8.2: Signal and background event numbers at modified selection level with CNN cut estimated from a BNB+Cosmic sample and Cosmic only sample normalized to $5 * 10^{19}$ PoT. The last column gives the fraction of this signal or background type to the total selected events per CNN probability.

Table 8.1 shows the passing rates for the 75 cm track length cut and the CNN cut at 70% and 83%. The passing rates at the track containment level for the 75 cm track length cut compared to the CNN are comparable with only a 0.6% difference in the in time cosmic bin which may be due in part to the larger in time cosmic statistics used for the CNN dataset. These passing rates need to be comparable to then be able to compare the passing rates after the CNN cut to the 75 cm cut. Again, the same BNB+Cosmic sample was used for both selection I modified with 75 cm cut and selection I modified with CNN cut. As it stands, a CNN cut at 83% probability has

1652 a MC true CC event passing rate of 14% compared to the 13% passing rate of the 75
 1653 cm track length cut. The Signal:Cosmic Only background is also reduced from 1:0.6
 1654 to 1:0.4 The total passing rate is also higher than the 75 cm cut, 3.6% vs 4.0%. Table
 1655 8.2 shows the breakdown of signal and backgrounds for the CNN at the different
 1656 probabilities. We have a 61% signal passing rate with the CNN cut @ 83% versus the
 1657 53.8% signal passing rate of the 75 cm cut.

1658 Based on these numbers, the following performance values of the modified selec-
 1659 tion with 75 cm cut versus modified selection with CNN @ 83% probability cut were
 1660 calculated:

- 1661 • Efficiency: Number of selected true ν_μ CC events divided by the number of
 1662 expected true ν_μ CC events with interaction in the FV.
 - 1663 – Selection I modified: 13%
 - 1664 – Selection I modified with CNN cut @ 83% probability: 14%
- 1665 • Purity: Number of selected true ν_μ CC events divided by sum of itself and the
 1666 number of all backgrounds.
 - 1667 – Selection I modified: 53.8%
 - 1668 – Selection I modified with CNN cut @ 83% probability: 61%

1669 Lastly, figure 8.12 shows a more representative performance of the CNN. Due to
 1670 the fact that the CNN was trained on muons and pions, showing the performance
 1671 of CC muon events versus NC pion events with respect to CNN probability gives a
 1672 better picture of how the network is performing. Figure 8.12 shows that at 83% we
 1673 are below the 75 cm cut NC pion threshold and still above the CC muon threshold.
 1674 Using 83% probability not only reduced the NC pion background, it also dramatically
 1675 reduced the in time cosmics and cosmics in the BNB.

1676 8.1.3 Conclusions and Future Work

1677 It was shown that even though CNN10000 was trained with single particle generated
 1678 muons and pions, it performs fairly well at classifying track candidate images from
 1679 BNB+Cosmic events. Events have been regained below the 75 cm track length cut and
 1680 the momentum and track range distributions have similar shapes to the distributions of
 1681 Selection I original and modified. Efficiencies and purities were calculated for selection

Table 8: **Selection I: Modified** Signal and background event numbers at modified selection level estimated from a BNB+Cosmic sample and Cosmic only sample normalized to 5×10^{19} PoT. The last column gives the fraction of this signal or background type to the total 2189 selected events.

Signal	#Events	
ν_μ CC events with true vertex in FV	1168	53.8%
Backgrounds		
Cosmics only events	725	33.4%
Cosmics in BNB events	144	6.6%
NC events	75	3.5%
ν_e and $\bar{\nu}_e$ events	4	0.2%
$\bar{\nu}_\mu$ events	15	0.7%
ν_μ CC events with true vertex outside FV	40	1.8%

Figure 8.11: Snapshot of signal and background event numbers of Selection I modified from cc-inclusive note [?]

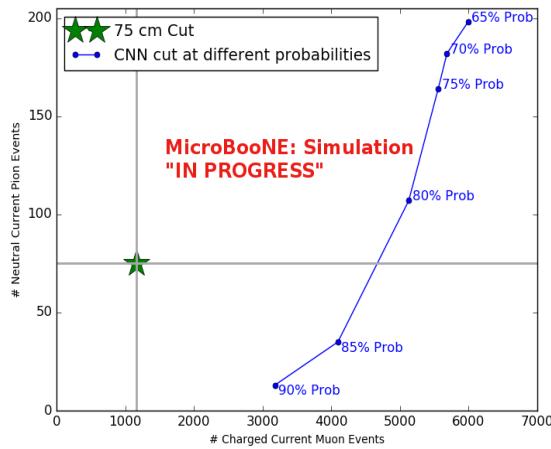

Figure 8.12: CNN performance of classified muons and pions compared to the already implemented 75 cm track length cut

1682 I modified events before 75 cm track length cut with the CNN at 83% probability and
1683 are 14% and 62% respectively. Although the CNN doesn't have separation between
1684 muons and pions and although all particles passing CNN are classified as muon,
1685 increasing CNN probability allows us to increase the purity as well as maintain an
1686 efficiency comparable to the 75 cm track length cut all while recovering events below
1687 that 75 cm cut. Out of the 6142 events that passed the CNN @ 83% 1470 events were
1688 below the 75 cm cut, a recovery of 3.3% of data with a purity of 15%. Although
1689 these numbers are low, it is an improvement from the selection I modified in both total
1690 efficiency and purity and an increase in phase space by recovering these events.

1691 **8.2 Classification using CNN100000**

1692 All future classifications will be done using Selection I Modified CC-Inclusive Filter
1693 because it has a higher efficiency and purity than Selection I Original CC-Inclusive
1694 Filter. To reiterate, CNN100000 was trained using 20,000 images of each $\mu/\pi/p/\gamma/e$.
1695 The results of using CNN100000 to classify BNB+Cosmics will be outlined below.

1696 **8.2.1 Classification of MC data using Selection I Modified 1697 CC-Inclusive Filter**

1698 **8.2.2 Classification of MicroBooNE data using Selection I Modified 1699 CC-Inclusive Filter**

1700 **8.2.3 Comparing two CC-Inclusive Cross Section Selection Filters**
